The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are *sharp*, the articles *short*, and the facts *authentic*, the contributions will receive special attention. Accepted articles will be paid for at regular space rates.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

High Speed Through the Ice Fields

THE Board of Trade inquiry into the loss of the "Titanic," which is being held under Lord Mersey, naturally is eliciting more detailed evidence than it was possible to gather during the necessarily limited investigation by our Senate Committee. Thus far, some very startling testimony has been given (startling at least to the lay mind) by certain of the more important witnesses. Mr. Ismay, for instance, gave an unqualified endorsement of the course followed by Capt. Smith, of the "Titanic," in proceeding at full speed after he had received several warnings that there was heavy ice ahead of the ship. The witness made the point that, by traveling at high speed, the "Titanic" would have been sooner through the zone of danger and out in clear water again. The argument is familiar. We have heard the same thing said in justification of traveling at high speed through a belt of fog.

So important is this testimony in the light which it throws on the risks of transatlantic travel, that we have made personal inquiry among the navigating officers of several first-class passenger ships, and we find that if the weather is clear, it is the universal practice not to slow down the ship, even though it be well known, through wireless despatches, that there is a field of ice ahead. "We never stop for ice in clear weather," said one officer of an English ship. "The course followed by Capt. Smith was perfectly justified," was the comment of the leading officer on one of the fastest German ships. Indeed, the consensus of this expert opinion, without an exception, justified the high speed of the "Titanic," as being in accordance with the recognized practice under such conditions on the bridge of all transatlantic steamships. It seems to be universally held that, if a good lookout is kept on such a clear night as that of April 14th, it is practically impossible to avoid seeing an iceberg, long before it gets into dangerous proximity to the ship. Obviously, then, one of the lessons of this disaster is that now and again, even though the night be clear, there will occur conditions, such as a smooth sea and an iceberg of a color that approximates to the general coloring of the sea, which may make it impossible to detect the ice in time to avoid collision, and so may render a repetition of the "Titanic" disaster inevitable.

It would seem from testimony given before the Board of Trade that conditions did render it extremely difficult to see this particular iceberg. One officer of the "Titanic" testified "everything was against us," meaning that the size of the iceberg, its color and the absence of broken water at its base, made it practically impossible to detect the obstruction until it was close aboard.

In our investigation, above referred to, we found a consensus of opinion, also, that the chances of avoiding the ice when it was once sighted were as good, if not better, when the ship was running at high speed than when she was running under a slow bell; it being claimed that the ship would answer her helm more quickly at high than she would at low speed; which is undoubtedly true.

Now, since the steamship companies wish their ships to be run at full speed, if possible, all the way across the Atlantic; since the officers in command of the ships are unanimously in favor of high speed; and since the public, except when it is in a panic over some portentous disaster, is certainly in favor of high speed; it is safe to assume that speed will not be slackened in the future, either in fog or among icebergs. Ships weighing from 40,000 to 70,000 tons will continue to go hurtling their way across the Atlantic, whether by night or by day, trusting to the sharp eye and the steady hand to avert disaster. Evidently, if travel is to be made absolutely safe, that is to say, if the "Titanics" of the future are not occasionally to be sent to the bottom at short warning, carrying a multitude of people with them, something should be done to make the ship unsinkable under those special conditions when "everything is against" the ship and the keen eye and the steady hand are not sufficient to prevent catastrophe.

The Board of Trade inquiry now going on in London will fail pitifully of its purpose, if it does not make such changes in the laws governing the structural requirements for safety in future ships as shall make them practically unsinkable by collision, whether with another ship, as in the case of the "Republic," or with ice, as in the case of the "Titanic," or with the derelict, as in the case of many a good ship that has sailed and never been heard of again.

Battle Efficiency and Navy Appropriations

THE reluctance of the House of Representatives to provide the necessary appropriations to carry out the very reasonable program for maintaining our Navy at its proper relative strength, looks like a very poor recognition of the high state of efficiency to which our existing fleets have been carried.

There may be other departments of the Government which can show an equal rate of improvement; but we are certain that there are none which can excel the record which has been made during the past two or three years by our Navy Department.

At the last analysis, the object of the money which has been spent and the infinite care, thought, patience, and hard work, which have so markedly characterized every branch of the Navy Department, is the maintenance on the high seas of a fleet of battleships and cruisers, characterized by the highest efficiency, and at all times ready for immediate action at the call of the Government.

Everyone who is at all familiar with conditions in the Navy to-day knows that this efficiency has been realized beyond the most sanguine expectations. Not only are the latest battleships which have gone into commission among the most powerful and most completely protected in the world, but the efficiency of these ships, as shown in target practice under battle conditions, is such as to warrant the belief that our gunners lead the world in the accuracy and rapidity of their fire at the longest ranges.

The fighting efficiency of our battleships of to-day, as compared with that of the fleet which fought under Sampson and Schley during the Spanish-American war, shows an improvement which is scarcely believable except by those who, like the writer, have had an opportunity to witness the work of the fleet from one of the battleships engaged. This improvement has been succinctly stated by Mr. Meyer, the Secretary of the Navy, more than once during the past few months. A comparison shows that, whereas the percentage of hits in 1898 was 3½ with the large guns, firing about once in five minutes at short range, the percentage of hits in the firing last year at the San Marcos was 33 1/3, the range being 10,000 yards, and the present rate of firing a single 12-inch gun being about ten shots in five minutes. This rather overestimates the work at Santiago and underestimates the work to-day. A roughly drawn comparison shows that we are about 1,200 times better in gunnery efficiency than we were at Santiago.

So far then as the ability of our battleships and cruisers to hit the enemy hard and often at great ranges is concerned, it is certain, if we may adopt a current phrase, that the country is "getting its money's worth." If the pruning knife of economy must be used, it would be wise, surely, to spare a tree which is yielding such abundant fruit.

A New Method of Testing Coal

AS a test of the value and character of fuel, the discovery of the amount of volatile matter in coal is unquestionably of the very greatest importance. This is estimated by finding the loss in weight of about fifteen grains of a sample, by bringing it to a high temperature in a platinum dish. This simple procedure really gives more information than any detailed chemical or calorimetric analysis.

However, the complete accuracy of the test is not always possible. The weight, length, breadth, and intensity of the flame and the heat, as well as the platinum receptacle which holds the sample, the sort of gas and burner, the distance, time, and other conditions, all have some effect upon the results, that is upon the residue left and the volatile matter driven off.

The committee on coal analysis of the American Chemical Society over twelve years ago made an exhaustive study of [illegible] in a report that the method [illegible] the amount of volatile [illegible] uniform plan to follow.

Usually the coke left behind is [illegible] ignored. The caking or swelling of the [illegible] mentioned, but no discussion of the kind [illegible] of the coal enters into consideration.

Dr. R. Lessing has just announced to the London Society of Chemical Industry a novel [illegible] plan, which will give a more correct [illegible] difference in the coke produced from various [illegible] which will account for the process of carbonization in all cases. It will show a qualitative distinction between the various types of coal, and eliminate the failings of the old method, the platinum dish test.

The sources of error in the old method may be said to be, first, elements which raised the volatile value, such as combustion of coke in the air rich in oxygen, and flickering coal dust due to the explosive gases of certain coals and rush of air currents caused by the flames. Secondly, the elements that decrease the volatile value, such as cessation of the action before the coal is thoroughly coked, deposit of the volatile materials on the walls of the platinum crucible, and decomposition of volatile substances by radiation.

The secondary breaking up of volatile substances, depends on the breadth of surface with which they come in contact. The coal in the platinum crucible is spread in a very thin layer. It takes up less than one tenth of the whole space. The gas and tar vapors touch a broader area than is good. In order to avoid the errors caused by waste space over the coal, and too much heated surface in contact with the gas and other volatile products in the crucible test, Dr. Lessing prefers to conduct his analysis with a small cylindrical vessel. He applies the heat to the coal itself, and not to the volatile products. By introducing a piston which rests on the powdered coal and fits loosely into the outer cylinder, all waste space is prevented, and all gases and vapors are allowed free play.

Dr. Lessing's apparatus consists of a heating tube, a quartz glass cylinder. This non-conducting medium may have an electric resistance coil of platinum wire wound directly around it. Numerous glass pin points are fused on this tube to keep the turns of the platinum coil apart. In order to concentrate the heat where it is required, the platinum wire is first wound to a close coil and this is wound around the cylinder tube. The coil attaches itself by its own elasticity. The coils are close at the bottom of the cylinder, getting wider and wider apart, so that the heat is just enough to keep the coal tar volatilized. Another "reacting" glass vessel fits loosely into the other "heating" tube. Its interval diameter is about one third of an inch.

Fifteen grains of the powdered coal are placed in the inner tube, and into a third tube which telescopes into the other inner tube. By altering the weight of this innermost tube or filling it with different amounts of quartz powder, during the test various pressures may be exerted on the coal.

The outermost tube is buried in an insulating substance such as kieselguhr. A rheostat combined with the furnace allows various changes of resistance and the temperature may be accordingly altered.

The test is made, by weighing the coal into the middle tube. Then the innermost tube is inserted over this and the two placed within the outside, insulated tube. As the current is turned into the platinum coil, the temperature slowly rises, allowing the gradations and steps of carbonization to be recorded. First, free moisture, then occluded gases, soon to be followed by tarry vapors, will be seen increasing in volume. All this depends upon the kind of coal tested. The heavier liquid tars and pitches condense on the cold parts of the innermost tube. The whole test requires about six minutes, and is then permitted to cool. The coke obtained shows the character of the coal.

Dr. Lessing's simple device also serves to identify the individual differences of each kind of coal. Any particular kind of coal will give at all times when treated under the same conditions, a coke identical in all respects with another specimen produced from the same sample.

"Although the principal consideration in designing the apparatus," says Dr. Lessing, "is to obtain a means for generally studying bituminous coals as fuel, satisfactory results have been obtained when employing it for a quantitative estimation of volatile matter."

Limits of Natural Vision.—The limits of vision vary with elevation, condition of the atmosphere, intensity of illumination and other modifying elements in different cases. On a clear day an object one foot above a level plain may be seen at the distance of 1.31 mile, one [illegible] feet high [illegible] miles, one 20 feet high [illegible] miles, one 100 feet high [illegible] miles; one a mile high, as the top of a mountain, [illegible] miles. This allows [illegible] inches for the curvature of the earth, and assumes that the size and illumination of the object are sufficient to produce an image [illegible].

[illegible]

[illegible] it is reported that [illegible] of starch are irradiated for several hours [illegible] of moderate penetrative power, the starch is [illegible] converted into soluble starch and dextrin, and [illegible] and viscosity of the solution are markedly [illegible]. An exposure of 5½ hours caused the transformation of about 5 per cent of the starch into dextrin.

The Montefiore Prize.—The conditions for the triennial Montefiore prize for the 1914 concourse are the following: The prize consisting of 3 per cent interest upon a Belgian fund of \$30,000, will be awarded every three years to the best original work presented upon scientific advancement and the progress made in technical applications of electricity in all departments, excluding popular treatises or simple compilations. This award is known as the George Montefiore Levi prize, and the jury is formed of ten electrical engineers, five home and five foreign, presided over by the chief professor of the Montefiore electro-technical institute. The last date for receiving contributions for the concourse is March 31st, 1914, and further information can be obtained from the secretary of the Montefiore association at Liege, Belgium, 31 rue Saint-Gilles.

Accuracy of Electric Meters Under Intermittent Loads.—Certain critical consumers of electrical energy who have noted that their electric meters keep on running for one or two seconds after the lights are turned out or the elevator or other motor is shut down, may have imagined that their meters were overcharging them by this action. These persons can have their fears allayed by the conclusions of a paper on "Electrical Meters under Variable Loads," recently read before the British Institution of Electrical Engineers, viz., that errors due to intermittent loads are relatively small in meters of the type generally used in the United States, designed with the Foucault braking disk. The fact is liable to be overlooked that the inertia of the meter, which causes the latter to run for a moment after the current is interrupted, will also tend to prevent the meter from starting for a moment after the circuit is closed.

Electricity from Peat.—European engineers are engaged at present in the investigation of methods of utilizing peat as fuel in electric stations. Southern Bavaria, for instance, has vast peat fields which would serve to run electric plants of large size and this would give a great reserve of power. The peat bogs lie mainly in the region of the Danube, and are estimated to cover an area of 500 square miles. Supposing the peat layer to be only 3 feet in thickness and the cubic foot of peat to afford but 3 pounds of fuel, this will mean a supply of 50 million tons. With the operation of extracting the peat regularly carried on during the year for 309 days, this can afford 700,000 horse-power in the space of 50 years. The fuel can be burned under boilers or it can be used in special producers to secure a supply of gas for industrial purposes.

Hydro-electric Plants in Iceland.—Iceland possesses a large amount of power in the shape of waterfalls, and for some time past the question of obtaining an electrical supply from them has been under consideration, but what makes the matter difficult is that most of the falls lie at great distances from the coast and are far from the centers of population. There are however many other falls which could be utilized. Quite recently a French syndicate purchased a large extent of ground in the neighborhood of Thorlakshaven, as well as several large waterfalls situated in the mountain regions in the interior. It is stated that the falls will be able to furnish as much as 200,000 horse-power. The present syndicate is to construct a good port upon its ground and it will furnish a supply of current to different industries which are situated in this district. One of the newest enterprises will be the construction of works for manufacturing nitrogenous products on the Birkeland-Eyde electric system.

Electric Light Service in Denmark.—According to recent information about the progress of electric light and power industries in Denmark, it appears that all the towns of 5,000 inhabitants and over are now provided with public electric service. As to towns lying between 5,000 and 3,000 inhabitants, there are only three in which electric mains are not installed, so that it will be seen that Denmark is one of the most progressive countries in this respect. The largest sized electric stations are to be found at Copenhagen, and at present there are three large plants in operation giving a total of 27,000 horse-power. Current is supplied for the city mains as well as for the tramway lines. As regards the Danish stations in small towns, in general each town has its own plant, and there is but one example of an interconnected system. This is at Skovshoved, near Copenhagen, and the [illegible] station extends its power lines over all the [illegible] also supplying the tramways of Hellerup and [illegible]. In most of the town electric stations the [illegible] is used.

Science

A Russian North Polar Expedition is being planned by Capt. Sedow, who has had considerable experience in exploring under Arctic conditions, having led an expedition to the mouth of the Kolyma in 1909, and one to Nova Zembla in 1910. Sedow proposes to proceed in a ship to Franz Josef Land, and thence to attempt a sledge journey over the ice to Greenland, by way of the pole. He has announced his intention of naming any land he may find near the pole "Nicholas II Land," and thus counts on securing the patriotic support of the Russians to his undertaking. There has been some talk in the Russian Duma of providing the explorer with a government vessel, to be especially constructed for ice-crushing, in accordance with an old plan of the late Admiral Makaroff.

The Australasian Antarctic Expedition, under Dr. Mawson, has not only proved the existence, over a distance of some 1,200 miles, of Wilkes Land, which has been a bone of contention between American and European geographers for seventy-odd years, but has actually landed two parties on it; one, under Mawson himself, nearly at the east end of this coast, at Point Alden, in the eastern part of Adelie Land; the other, under Mr. Wild, about 1,200 miles farther west, in the part of the coast that was named by Wilkes Termination Land, and that has hitherto been either ignored or marked with a note of interrogation on all European maps. The landing of Mr. Wild's party was accomplished with great difficulty, on the precipitous ice-cliff of a glacier about 100 feet high. A year's stores had to be hoisted to the top by means of shear-legs. Besides these two parties in Antarctica, the expedition landed five men at Macquarie Island, where a wireless telegraph station was installed. The "Aurora," the ship of the expedition, finally sailed back to civilization, and will return to relieve the exploring parties in the southern summer of 1912-13. Meantime, she will carry on oceanographic research—for which she is specially equipped—to the south of Australia.

Sea Routes to Siberia.—Contrary to previous reports, it now appears that the plans of the English captain, Webster, to establish regular steamship communication between European ports and northwestern Siberia by way of the Arctic Ocean and Kara Sea have been disapproved by the Russian government, obviously for the reason that this bold undertaking, which appeared to be entirely feasible, would have diverted considerable traffic from the trans-Siberian railway. On the other hand, the Russian authorities are furthering in every way the establishment of communication by sea between Pacific ports and northwestern Siberia, *via* Bering Strait. A surveying party, under Capt. Grünfeld, has proceeded from Yakutsk to Nishni Kolymsk, at the mouth of the Kolyma River, to make a thorough investigation of that port, and the geologist, J. P. Tolmatschew, will study the conditions of navigation between the mouths of the Kolyma and the Lena, including an examination of the Lena delta, with a view to establishing a sea route to the latter region. The ice-breakers "Taimyr" and "Waigatsch" were to leave Vladivostok in May for a surveying expedition along the coast of Kamtchatka, after which they will proceed *via* Bering Strait to the Arctic coast of Siberia for a cruise at least as far west as the Lena. If ice conditions prove favorable these vessels will attempt to pass Cape Chelyuskin and accomplish the northeast passage to the European port of Archangel.

An Elixir of Life.—At a recent meeting of the French Academy of Sciences, Prof. Metchnikoff, Director of the Pasteur Institute, gave a fascinating account of another advance in his struggle against the factors causing senility. Recent scientific research has shown the natural decay of the human body to be brought about by the bacterial flora of the intestines. The fact that the Bulgarian peasants feeding partly on yoghurt, a fermented product of cow milk, reach an astounding longevity, is accounted for by the invasion of beneficent bacteria taking the place of the harmful inhabitants of our digestive organs. Arteriosclerosis, sclerosis of the liver and an inflammation of the kidneys are the three maladies produced according to Metchnikoff by the poisonous action of our bacteria. Experiments on animals have shown the two toxins *indol* and *phenol*, which are responsible for this poisoning of the body, to be eliminated by food rich in sugar, such as dates, bananas, etc., the sugar destroying the poison. As, however, the sugar, being absorbed in the upper parts of the intestines, does not penetrate as far as the large intestine, which contains these dangerous toxins, means had to be designed for introducing sugar into that part of the alimentary canal. Such a means has now been found in a beneficent microbe derived from the bacterial flora of dogs and which, especially if assisted by an abundant consumption of potatoes and by some lactic ferment, will prevent the production of toxin. These experiments, in Prof. Metchnikoff's own words, are the first step toward the conversion of our bacterial vegetation from a "wild" flora into a cultivated harmless flora.

Aeronautics

The Death of Harry Turner.—Harry Turner, a nineteen-year-old mechanic in the employ of an aviator in Mineola, was killed recently in his employer's machine. He was making a circle above the field when he attempted to descend. It is not very clear how the accident occurred. Apparently it was due to bad handling.

The First Navy Zeppelin.—The German navy is to have its first Zeppelin airship. Hitherto, the rigid dirigibles of Count Zeppelin have been used by the army and by a private company for the transportation of passengers. In its official tests, the navy Zeppelin will be required to remain aloft continuously for twenty hours and to carry one ton of explosives. Most of the Zeppelins are now equipped with wireless apparatus.

A Parachute Drop from an Aeroplane.—The first successful parachute drop from a flying machine was made on Long Island by a venturesome young man named Law, who has been startling the residents of New York by leaping from tall buildings, in a parachute. Law went up with an aviator in a biplane. The parachute was attached to the under side of the lower plane. While the accounts that have been given of the exploit are not very clear, it seems that Law crawled under the plane hand over hand until he managed to seize the parachute.

Some Recent German Aviation Exploits.—It is curious that we hear so little in this country of some of the more remarkable achievements of German aviators. How many people in this country know of the recent flight from Berlin to Vienna by Hirth with a passenger, in which a mountain range 4,500 feet high was crossed and in which an average speed of more than sixty miles an hour was maintained? It may interest those readers of the SCIENTIFIC AMERICAN who have been following our articles on the GOULD-SCIENTIFIC AMERICAN Prize that the machine was equipped with two motors and two propellers.

Aviation Insurance.—According to United States Consul General A. M. Thackara of Berlin, the business of insuring the limbs and lives of aviators is not very prosperous in Germany. The rate for the insurance of those who go up in balloons and dirigibles has recently been increased, while insurance for those who go up in aeroplanes is simply unobtainable. "None of the local companies will now quote rates for the insurance of aviators against death. The rates for accident insurance for aviators are \$2.38 for a \$238 policy and \$1.76 for a policy *yielding* a daily remuneration of twenty-four cents during invalidity. The rates for the insurance of aviators against liability for damages arising from injury to other persons range from \$29.75 for a policy paying a maximum of \$5,950 when one person is injured or \$17,850 when more than one is injured, to \$47.60 for a maximum of \$23,800 for one or \$71,400 for more than one person injured. The rate for insurance against liability for damages to property is 20 per cent of the policy when damages from fire or explosion are not included and 30 per cent when such damages are included. The minimum premium is \$2.38 and the maximum liability \$2,380. The rules governing this form of insurance are in general the same as those usually covering other forms of insurance against liability for damages. Insurance against accident of those who go up in motorless balloons as in the case of aeroplane accident insurance is usually written in connection with ordinary accident insurance. The rates for this combined insurance are the same as for ordinary accident insurance plus the rate quoted above."

The Naval Aeroplane.—In a book entitled "Aviation in the Navy," Lieut. E. Lapointe of the French navy discusses the relative merits of the hydro-aeroplane and of the aeroplane which starts from and alights on the deck of a battleship. He points out that the hydro-aeroplane is not favored by sailors because it is useful only in absolutely still water. To alight on the water, he argues, is no great advantage except perhaps for a great aeroplane acting independently of a ship and attempting to make a protracted cruise. He proposes that a competition be held for a naval aeroplane which, by means of special floats, watertight bodies, or even fixed wings serving as floats, has the ability to float on a moderate sea and in a moderate breeze for several hours without injury to passengers or machinery. The motor must be of such construction that, after several hours in this position, it can be overhauled and put in operation in a few minutes. It must be possible to hoist the machine from the water and land it on a ship's deck by the ship's crane. It must be able to start from or land upon the shore under ordinary conditions. Lieut. Lapointe distinguishes between an aeroplane scout to carry two passengers, a pilot and an observer, for three hours with an extra weight of 100 pounds, giving a total weight carried of 400 pounds, exclusive of necessary oil and gasoline for the motor, and an aeroplane cruiser which shall carry three passengers, a pilot, a mechanic and an observer, for at least five hours, with an extra load of 200 pounds, giving a total weight carried of 670 pounds, exclusive of necessary oil and gasoline for the motor.

The 11-inch howitzer is hauled by motor cars.

A New Type of Powerful Mortar

The Krupp Eleven-inch Howitzer and Portable Carriage

By the English Correspondent of the Scientific American

OWING to the development that has taken place in the design and construction of protective works in connection with fortifications, where ever-increasing strength is secured to the point almost of invulnerability, there has been a demand for more powerful and heavier weapons of attack. There is no doubt but that in the next war between any two of the foremost powers, greater stress will be laid upon the artillery. The war between Russia and Japan emphasized this factor to a convincing degree when, although the Japanese brought the latest skill in military science to bear upon Port Arthur, they made but little impression with their fire upon the permanent works. This attack was remarkable for the fact that in the attack the Japanese employed the heaviest arm that has ever been directed against fortifications—a 28-centimeter or 11-inch mortar.

In Russia, Austria-Hungary and France weapons of this type of 23, 24, and 27 centimeters, respectively, are in service, but in every instance they are practically permanent defense pieces, demanding a solid firing platform. Accordingly, if the occasion arises for the arm to be removed from one point to another, the operation is one of great difficulty and occupies considerable time.

Realizing this deficiency in mobility, the Krupp firm has designed a new type of mortar of this character, the outstanding feature of which is that it is mounted upon a gun carriage, so that it can be moved from point to point, and can even be attached to the artillery in field operations. This end is achieved without any sacrifice of ballistic efficiency, by the application of a long invariable recoil, and by the employment of wheels fitted with feet after the manner of the Diplock pedrail.

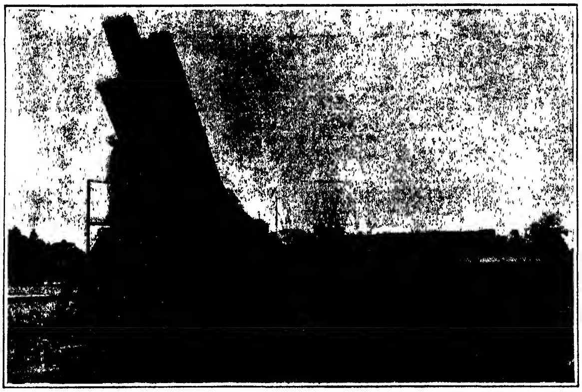
The Krupp designation of this piece as a howitzer is to distinguish it from the mortar proper, reserving the latter title for those weapons able to fire at an angle exceeding 45 degrees. This new arm has a greater variation in its elevation, so that it really is more flexible in use. The two terms however are now so generally confounded that it may be classed as a mortar.

The barrel is made of steel and comprises the inner bore and a jacket, the total length being 11 feet. The opening and closing of the breech is effected by turning a handle through a horizontal arc for about 135 degrees, and there is a safety device operated by hand to prevent premature firing or the accidental opening of the breech. After the discharge, the spent cartridge is automatically ejected by the opening of the breech block. Owing to the principle of construction, the opening and closing of the breech can be effected easily by one hand and in a few seconds, notwithstanding that it weighs over 1,100 pounds.

The carriage upon which the arm is mounted comprises in reality two vehicles. The barrel or mortar proper is carried upon one carriage, while the other carries the mounting with the recoil brake and the two air reservoirs. In transport the two pieces are hauled separately, the main wheels of each carriage being shod with feet, so as to permit passage over soft ground without sinking, while haulage is carried out by gasoline motor cars, as being more suited to the work than horses. Upon arriving at the position of firing, the mounting carriage is planted first, and then the second carriage is moved up from the rear, until the bore is in line with the cradle of the mounting. By means of thin wire cables and pulleys the mortar is pulled from its own carriage, and slides over special guides through the opening in the second carriage, until it is in the designed position, where it is made fast and connected up. The second carriage is then withdrawn, leaving the arm complete upon the mounting carriage and ready for firing.

The training gear gives a maximum elevation to the mortar of 65 degrees and works upon a rapid system. The weapon can also be moved 5 degrees on either side in the horizontal plane. The upper part of the cradle into which the bore slides carries a group of three cylinders. The central cylinder is the recoil brake, while that on either side is an air reservoir. The recoil brake differs from the type adopted in connection with field guns. The gun is not connected to the brake cylinders but to the piston rod. Consequently, it is the piston rod and the piston which move in the recoil of the gun, the brake cylinder remaining stationary. The air reservoirs consist essentially of an air cylinder, a ram with piston rod and piston, and valves.

The howitzer fires a shell weighing 136 pounds, and the charging of the weapon requires the aid of six or eight men, the explosive charge weighing 38 pounds. By using one of eight different charges, it is possible to vary the initial velocity from 590 to 1,115 feet per second. It is possible to secure, with all distances exceeding 7,218 feet a falling angle for the shell exceeding 22 degrees. The weight of the projectile is more than twice that of the next most powerful weapon of its class, while its range is 20 per cent higher.



The mortar being transferred from its transport cradle to the mounting.

Bore, 11 inches, length, 11 feet, shell, 136 pounds, powder, 38 pounds, maximum elevation, 65 degrees; maximum range at 65 degrees 24,278 feet, maximum range at 42½ degrees, 33,185 feet.

A mobile 11-inch mortar for field service.

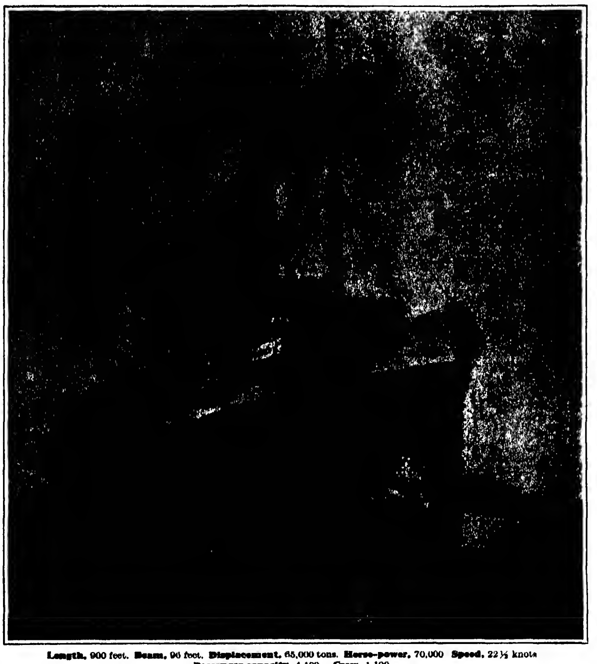
The Largest Ship Yet Constructed

The Launch of the 65,000 Ton Liner "Imperator"

WITH the loss of the "Titanic" fresh in the public mind, special interest attaches to the recent launch of the "Imperator," which exceeds that huge vessel by some 5,000 tons. The ship is being built for the Hamburg-American Company at the Vulcan Yard at Hamburg, and the ceremony of naming the ship at the launching was performed by the Kaiser, whose interest in the German merchant marine is second only to that which he has shown in the upbuilding of the German navy.

The length of the "Imperator" is 900 feet, and she thus has the distinction of being the first ship to come within 100 feet of the 1,000-foot ship of which naval architects have been wont to speak in late years in naming the possibilities of length which might be reached before many years have passed. Her beam is 96 feet and her molded depth 62 feet. From the keel to the boat deck will be 100 feet and the distance from the keel to the trucks of the masts will be 246 feet. The three funnels will be oval in section, measuring 18 feet on the smaller and 29 feet on the greater axis. The rudder will weigh 90 tons and the diameter of the rudder stock will be 2½ feet.

The ship will be driven by turbines of 70,000 horse-power which will be developed on four shafts,



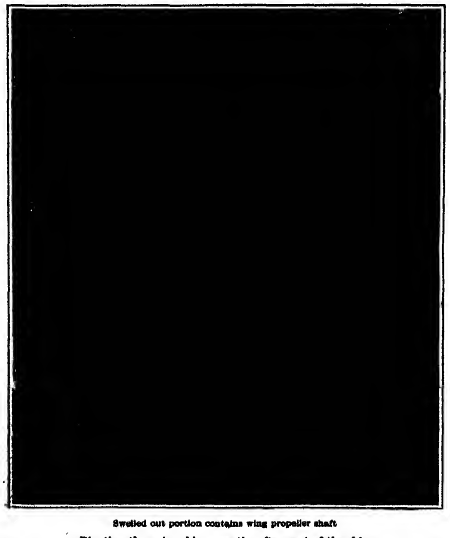
Length, 900 feet. **Beam**, 96 feet. **Displacement**, 65,000 tons. **Horse-power**, 70,000 **Speed**, 22½ knots **Passenger capacity**, 4,100 **Crew**, 1,100

The "Imperator"—largest ship afloat to-day.

and the estimated speed of the ship is 22½ knots. She will be equipped with water-tube boilers.

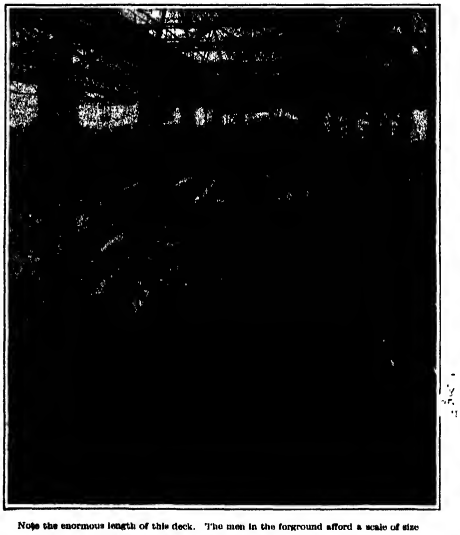
A feature of the ship which will be appreciated by passengers is that she will be fitted with the Frahm anti-rolling tanks, otherwise known from their shape as "U" tanks. This device consists of tanks of large capacity, built on opposite sides of the vessel and connected by an inclosed waterway, through which the water can flow from side to side of the ship as she rolls, its flow being subject to control by valves. Experience in the few passenger ships which have been thus equipped has shown the Frahm tanks to be the most efficient anti-rolling device yet tried.

With the "Titanic" disaster so recent a fact, the questions which at once arise with regard to the "Imperator" are those relating to her internal construction and particularly her construction below the water line. What provision has been made for meeting such a devastating accident as that which sent the huge "Titanic" to the bottom in two hours and thirty minutes? It will be remembered that in our article in the SCIENTIFIC AMERICAN of May 11th, we advocated either the use of a double skin below the water line, or the construction of longitudinal bulkheads to inclose coal bunkers carried along the sides of the vessel in the



Swelled out portion contains wing propeller shaft

Riveting the outer skin upon the after part of the ship.



Note the enormous length of this deck. The men in the forground afford a scale of size

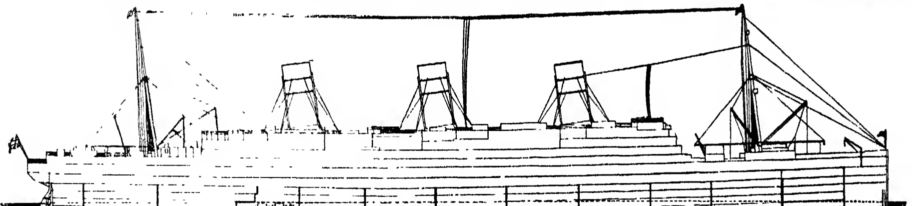
Laying the steel plating upon the deck beams.

wake of the boiler rooms. The sub-division of the "Imperator" below the water line has been carried out under the supervision of the Germanic Lloyd's and the Immigration authorities. It consists of a series of intersecting transverse and longitudinal bulkheads. Transversely, the ship is subdivided by twelve bulkheads, which are carried two decks above the water line, with the exception of the collision bulkhead forward, which extends four decks above the same level. These bulkheads are intersected by longitudinal bulkheads, which subdivide the boiler and engine rooms, the under water portion of the ship being divided altogether into twenty-four separate watertight compartments. There are four boiler rooms, containing the water-tube boilers, the type used on this ship. The coal bunkers are placed above the boiler rooms, and along the sides of the ship, in the latter case being known as wing bunkers. The longitudinal bulkheads are placed about nineteen or twenty feet in from the side of the ship, and they extend from bulkhead No. 4, aft to bulkhead No. 8. Astern of the aftermost boiler room is the forward turbine engine room, which is protected against flooding by two wing bulkheads, between which and the sides of the ship are placed the auxiliaries. The after turbine room is divided by a central longitudinal bulkhead.

Because of its great size, special interest attaches to the turbine installation. We present illustrations of one of the low-pressure turbines, from which one can gain a vivid impression of the great size and weight of the various parts. The rotor, or rotating part, contains 50,000 blades, and is capable of developing over 22,000 horse-power. The casing is 18 feet in diameter and 25 feet long. The shafting of all four propellers is 1½ feet in diameter. The propellers, which are made of turbadium bronze, are 16 feet 8 inches in diameter. Although the engines are spoken of as being of 70,000 horse-power, it is probable that on test they will develop from 80,000 to 85,000 horse-power.

The German government, in its supervision of the construction of passenger-carrying ships, pays as much attention to the question of fire-protection as it does to that of protection against sinking at sea. The tiers of passenger decks on a huge ship of the size of the "Imperator" are filled with a great amount of material of a highly combustible character, such as wainscotting, passenger stateroom partitions, paint, varnish, and general architectural embellishment. This material would afford highly inflammable fuel, should a fire once obtain a strong hold upon the ship; and the long alleyways, if they were not shut off at intervals by the screens, would afford an easy means for the spread of fire throughout the full length of the deck. To prevent this, light steel bulkheads are run from side to side of the ship throughout the passenger accommodation spaces. They are provided with fire doors and drills are held at regular intervals, in which the fire mains are in full service, and the work of closing the smoke doors is carried through by such members of the crew as are detailed for this work.

We are informed by the Hamburg-American Company that the "Imperator" will probably make her maiden trip to New York in the early summer of 1913.



The transverse bulkheads amidship are carried two decks above the water line, the height increasing toward the ends. There are twenty-four watertight compartments below water.

Inboard profile of the "Imperator."

The Interferometer Barograph

A NEW device for observing and measuring minute fluctuations in atmospheric pressure is described by Prof. Albert C. Crehore and Major George O. Squier, U. S. A., in the *Bulletin of the Mount Weather Observatory*. The detection of these fluctuations, which occur unceasingly, is a problem that is attracting increasing attention, both from meteorologists and aeronauts. The first apparatus for the purpose was the Shaw-Dines microbarograph; another was the variograph, introduced two years ago by Schmidt. The principle of the Crehore-Squier instrument, however, is entirely new. The apparatus includes a set of eight standard aneroid cells, from which the air is exhausted, such as are used in the familiar Richard barograph. In the latter the recording apparatus consists of a system of mechanical levers and a pen, registering on a revolving cylinder. The "lost motion" attending any such combination of levers and pivots in the nature of things obliterates all of the delicate and rapid motions that would occur in the cells if they were disconnected from the recording apparatus, so that only the grosser changes of pressure are indicated. The new instrument makes its record by the interference of light. A plane glass plate, silvered on its upper surface, is fixed horizontally on top of the uppermost aneroid cell, and rises and falls with it. A second glass plate, thinly silvered on the under side, is fixed rigidly above and parallel to the moving plate; the two plates form the interference system. The source of light is a mercury vapor lamp placed almost directly above the interference plates. A camera is so adjusted as to photograph the circular interference bands through a slit, the resulting image being a strip along a diameter of the circles. The image is impressed upon a film moving at a uniform rate. As the circles expand and contract, with changes in pressure, each interference band makes its record as a wavy or sinuous line. The exact time is registered on the film by the device of interrupting the light for an instant at the end of each minute. The motion of the cells is magnified, by this device, about 50,000 times.

Phosphorus Slag as an Insecticide

THE slag or dross formed in the removal of phosphorus from iron ore has been for years used as a fertilizer, on account of the phosphorus that it contains, and also on account of the lime. Recent investigation has shown that the use of this slag is even more profitable than had at first been supposed.

The cultivation of the sugar beet in Germany suffers great damage from the plant louse. The depredations of these bugs are destructive to a large number of plants. All mixtures or liquors used for spraying plants as a protection against these insects have been applied in vain. The "false brown rust" or "curl" of the peach is caused by the plant lice, and it cannot be successfully fought because neither liquors nor powders can be made to reach the little animals. When the beet plant is attacked, the leaf curls up and protects the insect against any treatment the farmer may apply.

It has been found that by the application of large quantities of nitrates after rains, the beet is stimulated to push out new leaves, which take the place of those destroyed by the plant lice. But this method has its dangers since an excess of nitrogen in the soil may be just as harmful to the plants as the action of the insects. J. P. Wagner, a sugar beet expert, recently told the National Society of Agriculture in France of a successful attempt to fight these insects by means of phosphorus slag. He spread about 1,400 pounds of the phosphorus slag to the acre on fields that were infested with the plant louse. Not only did this treatment prevent the insects from attacking the leaves, but they were driven away from leaves they had already attacked. On another field the slag was applied in larger quantities. Every plant was already attacked by the insects when the dross was applied. Within eight days all the insects had disappeared, and the plants recovered their healthy appearance and color.

The method by which the phosphorus slag operated in these cases is not known. Wagner thinks that the compound forms a thin layer on the leaf, spreading out over the whole surface, and that it is either distasteful or injurious to the insect. It is well known that many lime compounds are injurious to animals with soft, naked skins such as snails, caterpillars, naked larvæ; but it has not been shown that a similar effect is actually produced in the treatment against plant lice with phosphorus slag.

The Foundering of a Japanese Submarine

A Remarkable Letter

ON April 16th last, submarine No. 6 of the Imperial Japanese navy was lost while manuvering in Hiroshima Bay and all on board perished. She was commanded by Lieut. Takuma Faotomu, and after the vessel was raised, a letter of farewell from him was found in her conning tower. This remarkable document will be read with interest. The translation from the original published in the Japanese press, appeared in the Kobe *Herald*, and is as follows:

"Although there is indeed no excuse to make for the sinking of his Imperial Majesty's boat, and for the doing away of subordinates through my heedlessness, all on board the boat have discharged their duties well and in everything acted calmly until death. Although we are departing in pursuance of our duty to the state the only regret we have is due to anxiety lest the men of the world misunderstand the matter, and that thereby a blow may be given to the future development of the submarines.

Gentlemen, we hope you will be increasingly diligent without misunderstanding the cause of the accident, and that you will devote your full strength to investigate everything, and so secure the future development of submarines. If this be done we shall have nothing to regret.

"While going through gasoline submarine exercise we submerged too far, and when we attempted to shut the sluice valve, the chain in the meantime gave way.

"Then we tried to close the sluice valve by hand, but it was then too late, the rear part being full of water, and the boat sank at an angle of about 25 degrees. The boat rested at an incline of about 12 degrees pointing toward the stern. The switchboard being under water the electric lights gave out. Offensive gas developed and respiration became difficult. About 10 A. M. on the 15th the boat sank, and under this offensive gas we endeavored to expel the water by hand pumps.

"At the same time the vessel was being submerged we expelled the water from the main tank. The light having gone out the gage cannot be seen, but we know the water has been expelled from the main tank.

"We cannot use the electric current entirely; the electric liquid is overflowing, but no salt water has entered and chlorine gas has not developed. We only rely upon the hand pump now. The above has been written under the light of the conning tower, when it was about 11:45 o'clock. We are now soaked by the water which has made its way in. Our clothes are pretty wet and we feel cold. I had always been used to warn my shipmates that their behavior (on an emergency) should be calm and delicate, while brave; otherwise we could not hope for development and progress, and that at the same time one should not cultivate excessive delicacy, lest work should be retarded. People may be tempted to ridicule this after this failure, but I am perfectly confidant that my previous words have not been mistaken. The depth gage of the conning tower indicates 52 feet, and despite the endeavor to expel the water, the pump stopped, and did not work after 12 o'clock. The depth in this neighborhood being 10 fathoms, the reading may be correct.

"The officers and men of submarines must be appointed from the most distinguished among the distinguished, or there will be annoyance in cases like this. Happily all the members of this crew have discharged their duties well, and I am satisfied. I have always expected death whenever I left my home, and therefore my will is already in the drawer at Karasaki. (This remark applies only to my private affairs, and it is not necessary. Messrs. Taguchi and Asami please inform my father of this).

"I respectfully request that none of the families left by my subordinates shall suffer. The only thing I am anxious about is this. (Atmospheric pressure is increasing, and I feel as if my tympanum were breaking).

"12:30 o'clock, respiration is extraordinary difficult. I mean I am breathing gasoline. I am intoxicated with gasoline.

"It is 12:40 o'clock."

Correspondence

[The editors are not responsible for statements made in the correspondence column. Anonymous communications cannot be considered, but the names of correspondents will be withheld when so desired.]

The Wright Machine in the National Museum

To the Editor of the SCIENTIFIC AMERICAN:

Referring to the suggestion in "Aeronautics" column of a recent issue of the SCIENTIFIC AMERICAN that a national museum should acquire an early Wright flying machine, it may interest you to know that the machine which the Wright brothers flew at Fort Myer (Washington) drill grounds, and which was bought by the Government, now hangs in the old building of the National Museum, having been placed there by the War Department.

Washington, D. C. C. FRANCIS JENKINS.

Taxing the Professional Man

To the Editor of the SCIENTIFIC AMERICAN:

Replying to your question in the number for May 4th, page 394, first column: "What State levies a tax on members of the bar, or, indeed, of any profession?" permit me to say that for eight years, previous to a few years ago, I carried on business as a professional photographer at Newport News, Va., and that I paid an annual license fee of $51,75 for this privilege; part of this fee being for the city and part for the State. It was my understanding then that most, if not all, the professions, including the bar, were thus required to pay a license fee. And this was a charge in addition to any tax on property, both real and personal, including sewing machines and Bowie knives.

I think that this license taxation obtains in other Southern States besides Virginia.

Haines Falls, N. Y. SAMUEL E. RUSK.

Oregon's Roads

To the Editor of the SCIENTIFIC AMERICAN:

In reading your Good Roads number of March 16th, I find on page 240 the statement that you were unable to secure any information from the State authorities. You also state that the total mileage is less than 30,000.

I will be pleased to furnish you any information you may wish in the future, but I wish to correct the figures quoted by you Oregon had 34,258 miles of public highway in 1904, according to the United States Public Roads bulletins. My data are not quite complete, but a conservative estimate gives the State practically 40,000 miles to-day. About $3,000,000 was spent last year by the different counties and road districts.

Two sets of highway bills have been prepared for initiative action this year, both creating the office of State highway engineer One gives him absolute authority and empowers the State to issue bonds, the other makes him an advisory officer and leaves the bond issues to the separate counties.

Corvallis, Ore E. F. AYRES, Highway Engineer.

The Nut Problem Once More

[Those of our readers who have been following the correspondence on the problem originally published on page 174 (February 24th, 1912) will be interested in the letter reproduced below.—ED.]

To the Editor of the SCIENTIFIC AMERICAN:

I offer the following solution of the equation

$$A = 3\frac{53}{1024}F + 1\frac{452}{1024}$$

which seems to me to be more complete than the one you give in your Notes and Queries column, vol. cvi., No. 17, page 390:

$$A = 3F + 1 + \frac{53F + 452}{1024},$$

To find what integral value of F will make the fractional part integral, let

$$\frac{53F + 452}{1024} = M \text{ (integral)}$$

$$53F + 452 = 1024M$$

$$F = \frac{1024M - 452}{53} = 19M - 8 + \frac{17M - 28}{53}$$

Repeating the process:

$$\frac{17M - 28}{53} = N \text{ (integral)}$$

$$17M - 28 = 53N$$

$$M = \frac{53N + 28}{17} = 3N + 1 + \frac{2N + 11}{17}$$

Again:

$$\frac{2N + 11}{17} = P \text{ (integral)}$$

$$2N + 11 = 17P$$

$$N = \frac{17P - 11}{2} = 8P - 5 + \frac{P - 1}{2}$$

From which it is obvious that $P = 1$ gives the smallest integral value for N and the other letters in order backward.

$P = 1$
$N = 3$
$M = 11$
$F = 204$
$A = 624 = 1/5$ (whole number of nuts) $- 1$.

Whole number of nuts = 3,121.

New Bedford, Mass. FREDERICK D. STETSON.

Is Oxygen a Drug?

To the Editor of the SCIENTIFIC AMERICAN:

I beg to refer to your editorial "'Doping' Athletes with Oxygen," in issue of April 6th. In the same you declare Sir Edwin's proposal, to feed the Marathon runner with oxygen as with soup and water, to be "amazingly unscientific." At the same time you make several citations, as "oxygen jag," in which "ideas swarm, but it is hard to seize them;" and several statements, such as "Oxygen is a 'drug' that 'dopes' the recipient, quite like many other drugs;" "pure oxygen is a stimulant," but "as with all stimulants, excessive and occasionless use is dangerous;" and you speak of "oxygen intoxication"

I would consider it in the interest of sound knowledge if you would kindly mention the authority you cite against Sir Edwin's statement, as well as the source of your information. Interested in the subject of oxygen as any man would be who takes good care of his life, and gathering my information from authorities which I believe to be leading, I beg to differ with your opinion The question whether or in what degree the designations "stimulant," "dope," and "drug" are proper to be used for oxygen should be cleared.

To say that oxygen is a "stimulant" is very nearly correct, but more correct is to say that it is "the physiological stimulant." My authority on hand is Verworn, who in his "Allgemeine Physiologie" frequently mentions oxygen as "the only physiological stimulant and energy producer of living organism"

Among the "all stimulants" in which you seem to class oxygen, is there any one that is a physiological necessity, or one that forms a predominant physiological condition of life, as is the case with oxygen? If oxygen is a stimulant, we cannot do without it; all others are stimulants without which we do better. Similarly, I would ask if among the "drugs" that are "dopes," used to increase cardiac action, or in some way to artificially raise vitality, to exhilarate, if among these "doping" substances there is one which is a normal constituent of our system, or which normally circulates in our body fluids? I can think of none, except perhaps adrenaline

My further contention is that oxygen in the case of a runner is not used as a stimulant, but as a corrective for "lack of oxygen" and "metabolic abnormalities," that such stimulant as you have reference to is not needed in the case of the runner, and that oxygen in the most natural way can only benefit and never endanger the exhausted individual.

The heart of a runner beats abnormally rapid, therefore the mechanical part of the work of the circulatory system is highly efficient and a cardiac stimulant is not required. The real danger for the runner are fatigue and exhaustion. These are due to the accumulation of fatigue products and to lack of oxygen. Fatigue products are dissimilatory products of incomplete combustion Principally lactic acid is known to be produced by the work of muscles. Both lactic acid and lack of oxygen are reciprocal in cause and consequence, i e., lack of oxygen, due to the extreme draught under which the respiratory process is placed, is the condition for the formation of products of incomplete combustion; and again, acid products (fatigue products, lactic acid) formed in the muscles and circulating through the blood, result in conditions averse to normal oxidation as well as to oxygen absorption; hence lack of oxygen. This is a pathologic condition which can be remedied to a great extent by increasing the *partial pressure of oxygen for respiration.* It should be remembered also that in the case of the short distance runner or of hard work, oxygen consumption increases to seven or eight times the normal If our system had enough flexibility to correspond, feeding such increased demand steadily, and if the acid products circulating in the blood and in the tissues of the lungs would not interfere with adequate oxygen absorption, the organism might continue to be satisfied with a twenty per cent oxygen atmosphere. But experience has shown that such is not the case. Therefore, respiratory processes are greatly assisted by higher oxygen tension in the lungs, and this is accomplished by adding to the air which the panting runner breathes, pure oxygen, or enabling him to take a few breaths of oxygen unmixed. Bnt this is not exactly stimulation, and should it be called so because it increases the vitality by combating fatigue, it is stimulation by just the substance which physiologically is wanted.

As a few authorities on the physiology of running, on fatigue products, and on pathology of lack of oxygen, I may mention Zuntz and Schumburg ("Physiologie des Marsches"), Loewy-Zuntz, Müller, Caspari ("Höhenklimer," etc), Verworn, Mosso, S Schrotter, Haldane and Smith, Martin H Fischer

Oxygen "intoxication" is a layman's expression, and seems to me misleading for the numerous readers of your scientifically recognized paper. In the above sense we can speak of a "waste products intoxication" and of an oxygen "disintoxication."

Moreover, the difference between the physiological stimulant and any other stimulant is besides that the first is normally and at a normal fixed rate absorbed by the blood and the latter abnormally and at a non-fixed rate. I cite Nagel's "Textbook on Physiology of Man," I 1, p. 84; Christian Bohr, "Blotgase und Respiratorischer Gaswechsel" "With increased tension (of oxygen) the increased absorption follows at reduced rates, and before atmospheric oxygen tension (in the blood) is reached an increase of tension has but little influence upon the absorbed amount of oxygen, at saturation with pure oxygen under a pressure of 760 millimeters red blood corpuscles absorb proportionally insignificantly more oxygen than at saturation with atmospheric air." And the same, p 216 "When breathing gas mixtures enriched with oxygen or pure oxygen under atmospheric pressure at not excessively long periods, oxygen absorption and carbon dioxide secretion do not show important deviation from the normal However respiration of pure oxygen under a pressure of three to four atmospheres or respiration of ordinary air under a pressure of fifteen to twenty atmospheres acts quickly deadly, as has been shown by P Bert"

This of course is a condition which can only be produced in a laboratory by the necessary paraphernalia. But the above should bear evidence that the runner, who is under oxygen starvation on account of the pathologic "fatigue" condition of his blood, and even a normal individual, whose blood should be of normal oxygen capacity, runs no risk in breathing pure oxygen for a while, and that the word "intoxication" is physiologically out of place.

The immediate effects of oxygen inhalation are not felt by the reflectory nerves; in other words, produce no sensation Any man who, in breathing oxygen at higher than aerial partial tension, feels exhilarated and like getting an "oxygen jag," is either subject to imagination or the gas contains some impurity that produces the effect.

The soup or any nutriment which the runner consumes during the run I would, rather than oxygen, consider a stimulant or a tonic The effect which these produce is more in the nature of satisfying the secretive functions of the system than of supplying energy The energy in such extreme strain depends on the body's stores Water and oxygen are in my opinion the most needed factors in the maintenance of the energetic and respiratory functions of the system under extreme strain during a period of several hours I am however puzzled by your reference to "nascent" oxygen. Has Sir Edwin really said so?

I would conclude that we may consider oxygen a stimulant or *the* physiologic stimulant, a nutriment, an energy producer, a life sustainer, a corrective of depleted metabolism, or in general term, an invigorator—it is all that by nature of the physiology of organized life; but we should not consider it a drug or a dope, an intoxicant or narcotic, nor a danger, if pure and not dry.

I would deem it a favor if you will give publicity to this very brief outline on the rôle of oxygen in the case of the runner.

New York city RICHARD VON FOREGGER.

[Most controversy is over terms and definitions, rather than over ideas Pure oxygen is a stimulant, in that it excites a diffused and transient increase of vitality and energy Stimulants are oftentimes "indicated" in disease, but the use of any stimulant beyond the body's physiological needs is intoxication ("jag" in the vernacular). A drug is a medicament ("dope" in the vulgate); pure oxygen is such in anemic coma, lobar pneumonia, etc. Pure oxygen is not a physiological stimulant, but atmospheric air (oxygen 20 + parts with nitrogen 80— parts) is a most salutary physiological remedy Hydrogen is not a physiological remedy, but hydrogen + oxygen (H_2O) is Carbon (like H and O) is a constituent of the body, but it is not a physiological remedy. However, C, H, and O in combination (as soup, for example) make up a physiological remedy. Phosphorus, sulphur, iron, are essential constituents of the body, but not physiological remedies The editorial writer would restate his main thesis that the drugging of Marathon runners (the race is of some 26 miles) with pure oxygen would tend to physical disaster, sooner or later, for the man thus stimulated beyond his natural powers; and would be most unfair to those competitors who depend frankly upon their own natural capabilities, adjusted to natural environment, for the victory. Lankester is not responsible for the term "nascent oxygen;" the editorial writer used it in the sense of "uncombined oxygen."]

A New Use for Potatoes

Raising Potatoes in Germany for Industrial Purposes

By H. C. Price

WITHIN the last ten years a new industry has sprung up in Germany which has already become of large commercial importance, namely, the drying of potatoes for stock food. This is done in potato-drying factories that are rapidly increasing in all parts of the empire. How rapid this increase has been is shown by the fact that in 1907 there were but 118 such factories in Germany and last year there were 404 in operation, notwithstanding the fact that in that time the potato crop of Germany was the poorest they have had for many seasons and the price unusually high.

German Potato Crop.

Germany grows nearly five times as many bushels of potatoes as the United States. They produce on the average two and one half times as large an area and the yield is twice as much per acre. In fact, only two other crops, those of rye and oats, surpass the potato crop in acreage in Germany. In America potatoes are grown exclusively for human food, but not so in Germany; immense quantities are grown for industrial purposes and used for manufacturing starch and denatured alcohol and for drying, all of which are important industries. The market quotations are given regularly for potatoes for eating purposes and potatoes for manufacturing purposes and the price of the latter, as a rule, is about two thirds that of the former.

Much attention is given to breeding potatoes for starch content and experiment stations are maintained in the various provinces to test the different varieties for yield of potatoes, yield of starch per acre, as well as per cent of starch content. The test this past season of one hundred and twenty-five varieties, showed a variation in the per cent of starch content in the different varieties grown under the same conditions of from 12 per cent to 25 per cent.

The Germans have paid particular attention to developing the starch content of the potato in order to increase its value for manufacturing purposes and in doing so frequently lose in size of tubers and yield per acre.

Development of the Drying.

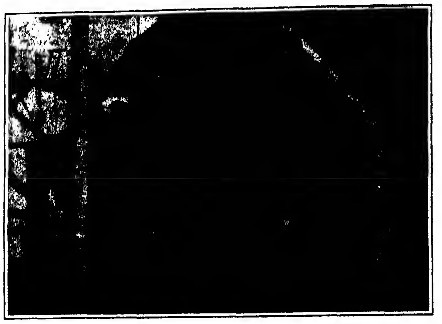
The development of the potato-drying industry has been the result of over-production and low prices. With such large areas grown, as is the case in Germany, in years of good crops there is a large over-production. In such years formerly the farmers were obliged to accept ruinously low prices for their crops and were at the mercy of the potato merchants. The potato being perishable, it cannot be carried over from one year to the next as is the case with grains. It is easily frozen and when once frozen is ruined, so that the disposition of a surplus in a good crop year was a serious problem.

For some years the Germans had been drying the sugar beet pulp from the sugar factories (after the sugar had been extracted) and using it as stock food. This gave rise to the suggestion of using the surplus potatoes in the same way. This would not only utilize the surplus but would preserve it in a form in which it could be held indefinitely and stored without danger of freezing. It would also take the surplus off the market and insure a reasonable price for the rest of the crop.

The government and the agricultural organizations offered large prizes in the latter part of the nineties for the most successful methods of preserving potatoes, both for human and stock food. As a result a large number of methods and kinds of apparatus were offered, so that it can be said by 1900 entirely successful methods had been perfected.

Two Methods Used.

There are two types of drying apparatus on the market. The one produces the so-called potato "schnitzel," which is made by shredding the raw potato into pieces about as thick as a small lead pencil and drying it under very intense heat. The other produces what is known as potato "flocken" flakes. In this latter method the potatoes are first cooked by steaming and then mashed and dried by passing between hot rollers by steam. Since the rollers are placed near to one another, the mass passes between like a sheet of paper. The heat causes them to adhere to the exterior walls of the rollers and the motion is so regulated that they are completely dried before the rollers have half completed the revolution. Two knives on the outside of the rollers cut off the dried mass, which has a bright yellowish-white appearance, a good smell, and forms a coarse sort of potato meal.



Apparatus for manufacturing flocken.

A potato-drying factory in Germany.

One type of potato-drying machinery.

In the drying of the raw potatoes, the shredded pieces are first exposed to very great temperatures, often as high as 1,000 deg. Cent (1,832 deg. Fahr.), as they are carried slowly through a long chamber with the temperature constantly decreasing. When they go into the drying chamber as raw potatoes they contain 75 to 80 per cent water, and when they come out as the dried product or "schnitzel" they contain 12 to 15 per cent water. In the manufacture of the flocken such high temperatures are not necessary, as the potatoes are first cooked, but when finished they contain approximately the same amount of water as the schnitzel.

The amount of raw potatoes required to produce one hundred pounds of the dried potatoes, depends upon the starch content and dry substance in the potatoes used, as well as upon the amount of moisture contained in the finished product. The following table shows the amount of dried potatoes, either as schnitzel or flocken, containing 15 per cent moisture that can be produced from potatoes of different qualities:

Amount of Raw Potatoes Required to Produce 100 Pounds of Dried Potatoes, Containing 15 Per Cent Moisture, and When They Contain

Per Cent.	Per Cent.	Lbs
12 starch	17.8 dry matter	480
14 "	19.8 " "	460
16 "	21.8 " "	390
18 "	23.8 " "	360
20 "	25.8 " "	330
22 "	27.8 " "	310
24 "	29.8 " "	290

Use of the Dried Potatoes.

The dried potatoes, both schnitzel and flocken, are used as food for horses, cattle, sheep and swine, and have come to be an important product on the market and are regularly quoted in all market reports. The potato flocken is preferred, as it is more digestible, and of the 404 factories in operation last year, 314 were equipped to manufacture flocken. That may be due in part to the fact that it does not cost as much to install an apparatus to manufacture potato flocken as it does to manufacture schnitzel. On the other hand, after the equipment has been installed, the potato schnitzel can be manufactured more cheaply than the flocken. The Germans count that it costs $1 to $1.50 per ton of fresh potatoes to dry them in the form of schnitzel and $2 to $2.50 per ton to dry them in the form of flocken.

Although dried potatoes may be used for all classes of livestock, as a matter of fact, they are used principally at the present time for swine. Experiments and practical experience have proven that dried potatoes may be used almost entirely to replace corn in the ration, and this is of decided advantage to Germany, since all the corn that is used has to be imported.

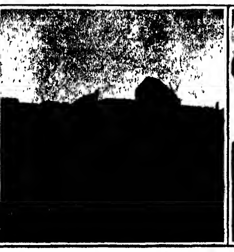
Advantages of the System.

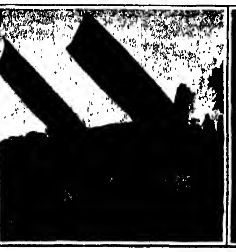
The extent to which potatoes are dried from year to year for stock food depends upon the crop. In years of over-production the surplus is dried and thus put into a form that can be preserved for an indefinite length of time. By drying the surplus the farmers are saved from ruinously low prices for their crops. In years of short crops, such as last year, it is used principally to utilize the culls and potatoes that are not suitable for human food. The dried potatoes are not only in a form that can be stored without danger of frost and for any length of time, but the weight is reduced about three-fourths, so that the cost of transportation is reduced in like proportion, and surplus in one section can be shipped to other sections of the country without great expense.

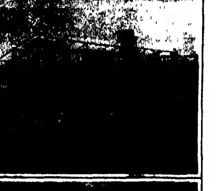
The system has passed the experimental stage and has taken a permanent place in the agricultural manufacturing industries of Germany.

The Failures of the "Aviettes"

Impossible Performances for an Impossible Prize







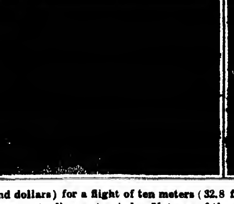
PERHAPS it was merely a desire for publicity, perhaps an exuberant sense of humor, that prompted Peugeot Frères to offer two prizes for flights made with the aid of human muscular energy alone. Surely at this late day no one, and least of all a firm of bicycle manufacturers, can plead gross ignorance of the first principles of cycling and of aviation, by offering a first prize of 10,000 francs for a machine which, propelled by human power alone, would cover a distance of 10 meters (32.8 feet) twice in opposite directions, and a second prize of 1,000 francs for a machine which would cover a distance of 1 meter (3.28 feet) at a height of 10 centimeters (about four inches).

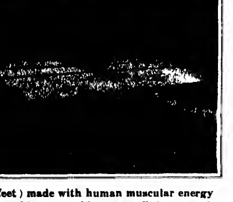
Although neither prize could possibly be won (the machines had to run on level ground, and having covered the prescribed distance, were to turn immediately and fly back to the starting point), Paris evinced an extraordinary interest in this *Concours de l'Aviette*. No less than one hundred and ninety-eight entries were received, but only twenty-three covetous aspirants to aviation fame appeared on the scene at the appointed hour. In the expectation of seeing a very novel contest, no less than two thousand five hundred people witnessed the futile attempts of most of the twenty-three to enrich themselves at the expense of Peugeot Frères. There was much hooting, much whistling, much jeering, and much mock encouragement.

The ignorance displayed by many of the designers of the machines entered is simply amazing. Even elementary principles were ignored. Almost every one of the machines that appeared at the Parc des Princes on June 2nd could not possibly get up a speed of more than fifteen miles an hour, so heavy were they. Wings had been mounted on bicycles, apparently with no conception of the relation of lifting effect to speed and area of supporting surface. Some of the machines were provided with elevating and vertical rudders; some had no guiding device of any kind, some were fitted with propellers, and some had no propellers at all. Apparently none of the men who entered realized that a regular motor-driven flying machine must have a speed of at least twenty-five miles an hour before it can vault into the air. Twenty-five miles an hour on a bicycle is a remarkably creditable performance. Riders who have made it know how considerable is the wind resistance encountered even at that rather moderate speed. The dramatic performances of men who have ridden behind railway trains (intended primarily to minimize air resistance) have evidently been without effect upon the general reading public. If a bicycle rider finds it difficult to travel at high speed on the open road, how is it possible for a man on an "aviette" to acquire a preliminary speed great enough for him to launch himself into the air, when at either side of the machine wings are to be found that have an area of forty square feet and that offer an enormous head-on resistance?

Obviously impossible as it was to rise from the ground even with a monoplane aviette, some of the contestants were foolish enough to attempt the feat with biplanes. An inventor named Piat, of Boulogne, for example, entered a biplane designed somewhat on the principle of a Farman machine. Another, from Montrouge, named Vincent, made attempt after attempt to win the 1,000-franc prize with a batlike machine fitted with double wings. Throughout the day he made effort after effort to get into the air. Again and again his friends started him off toward the track. The manner in which his performances were received by the crowd may be conjectured.

Although no one succeeded in leaving the ground, consolation silver medals were awarded to the sixteen men who trundled out their machines and had the courage of their convictions. The contest was supervised by a *Commission de l'Aviette*, consisting of Jacques Balsan, de Knyff, Etienne Giraud, Isaac Koechlin, Rodolphe Koechlin, Tissandier, Paul Rousseau, Frantz Reichel and Alibert. The prize offer remains open until the spring of 1913. It is said that another contest will take place some time in the month of October.





A French firm of bicycle makers offered a prize of ten thousand francs (two thousand dollars) for a flight of ten meters (32.8 feet) made with human muscular energy alone. One hundred and ninety-six machines were entered, of which twenty-three were actually constructed. Not one of the machines was able to get off the ground.

Club moss (*Selaginella*).

Horse-tail or scouring rush (*Equisetum*).

Common sweet pea.

A tip of one of the Indian hemps with fibrous bark and milky juice (*Apocynum*).

These specimens are inlaid on cardboard, the brilliancy of natural colors fully preserved and the mounting as smooth as a water color painting.

Preserving and Mounting Plant Specimens

How Pressure and Heat Can be Effectively Used

By Clara Reese

A SIMPLE and effective method of preserving plant specimens has been discovered. The process is likely to revolutionize the present slow and laborious preparing and mounting of herbarium collections. As a matter of scientific experiment the botanical department of the University of Pittsburgh, Pa., is giving the new process a trial.

The plant specimens to be mounted are brought in fresh and moist from garden or conservatory. These are subjected to a forced process of drying which preserves the natural colors of stem, leaf and flower. After this they are imbedded, or inlaid, on a yielding surface such as blotting paper, cardboard, silk, woolen or rubberized material, and when finished present the smoothness and evenness of a painting.

In demonstrating the process for me the inventor broke a leaf from a primrose plant in the presence of the writer. This leaf was laid smoothly on an ordinary piece of blotting paper. The blotting paper in turn was laid on a small steel plate neither much larger nor much thicker than a 5x7 camera negative. Several sheets of blotting paper were piled upon the primrose leaf to absorb the moisture and the whole laid upon the bed plate of an ordinary toggle press of hand leverage. A few steel plates were thrust in upon the blotters in order to build up the material to a thickness to meet the requirements of the press. Before applying the leverage, heat was introduced into the bed plate by means of a small pipe and a stopcock. The lever was forced down by hand, and at the expiration of thirty-five seconds, a cold draught succeeded the hot one in the bed plate, and the dried specimen was removed. It showed its original freshness, while the heat bath it received, somewhere about a temperature of 200 deg. Fahr., effectually destroyed all germ or insect life.

By immersing the card in cold water for an instant, the dried leaf slipped easily from the card. It was then laid upon the sheet to which it was to be permanently mounted or inlaid. Practically the same process in the toggle press for the permanent mounting was gone through with though "arms" were adjusted to the lever in order to give a higher degree of pressure and less heat was turned on in the bed plate. The inventor gives the completed specimens a final wash of liquid celluloid and alcohol as a protection to the same in case of rough handling.

The discoverer of the process is William Heeren, who has spent most of his lifetime as a skilled artificer in precious metals. Mr. Heeren appeared before the Botanical Society of Western Pennsylvania at a recent meeting and exhibited many of his imbedded specimens. As yet he has not succeeded in the inlaying of the natural plant in a ground of silver or gold, but he claims perfection so far as a yielding surface is concerned. He has hundreds of specimens and has subjected these to severe tests to prove the preserved colors as lasting and the inlaid growth as practically indestructible.

Mr. Heeren has kept his finished specimens under water for a week at a time and has lifted out the cards with their inlaid growth still unimpaired. He has imbedded his leaves and flowers in celluloid or transparent ground and hung them for months in the window in the sunlight as "transparencies." He has used his mountings as decorative lamp shades and as shades for electric bulbs and after a heated test of six months or more of household and office routine use, the roses, pansies, violets and ferns are as bright as ever in their first color. Others are hung where they are subjected to atmospheric changes.

This experimenter is equally successful in imbedding specimens whether of thick-stemmed and woody variety or of the most delicate and feathery of plant growth. He has inlaid clumps of moss and corsage bouquets of violets, and he has inlaid the delicate tracery of asparagus vine and the dainty petal of a rose. He has inlaid heads of grain, princess feathers and specimens of cattail, and he has likewise inlaid the ethereal quaker lady, the sweet pea and wood violet. There has really been no limitation in his experimentation, and sprays from bridal bouquets find themselves imbedded in small pieces of celluloid as ready for mounting as brooches and buckles.

A floral belt has a place in his experiment collection. In this instance the moss rose buds have been imbedded in a durable yielding strip of material. As the strip came from the hydraulic pressure, a corded ribbon of rich quality was laid over the strip and the whole put through a roller. The ribbon was then peeled off and the belt strip appears with its silken and corded markings. Many dainty "trimmings" of sheer material and silken fabric have their inlaying of delicate flower or vining. Mr. Heeren has not confined his experiments exclusively to plant growth, but butterflies and brilliant-hued insects are imbedded in a lasting manner. A most perfect and rich specimen of a peacock's feather is inlaid on a black rubber panel.

Mr. Heeren is not a botanist and will likely develop his discovery along ornamental lines as suitable to his craftsmanship. His workshop shows the ornamental trend in the grouping of blossoms and colors and ideas for fans, handbags, girdles, gift cards, brooches and buckles, likewise lamp shades and transparencies. The possibilities in these lines are endless.

Nevertheless, Mr. Heeren is making a herbarium by the usual process and is mounting specimens of plant growth the old way as a comparison with the new method. By the old plan the specimens are carefully arranged on bibulous paper, and pressed between smooth boards by putting weights or using a screw press. The paper is changed every day or two as the plants part with their moisture. When the process of desiccation is complete the specimens are fastened on sheets of paper by gummed strips. To protect these dried brown specimens from the ravages of insects, camphor is renewed frequently in the cabinets.

In his demonstration before the Botanical Society, Mr. Heeren contrasted the two methods and showed how the new way in the hands of botanical experts might bring a practical herbarium within reach of the ordinary class room without danger of mounted dried specimens breaking loose from cards or of destruction by insects. The "wash" given the inlaid cards preserves the specimens from inroads of insects. He showed how science might utilize the method likewise in a systematic arrangement for a large herbarium.

Mr. Heeren showed also how outlines might be printed for the youthful botanist to properly color. He deftly lifted an inlaid specimen out of its tight bed and showed how the matrix or impression might be used for printing an outline on drawing paper. He has examples of this outline printing as accurately defined as an engraving. In the hands of the skilled botanist, the inventor says, there is no reason why plant and flower should not be preserved in natural color and desired arrangement with much less waste of time, labor and space, than at present.

Mr. Heeren's discovery is the further development of an idea of his which is now classed as a successful invention, namely, the celluloid tags or number plates seen everywhere on the caps or coats of expressmen, messengers, porters and others in uniformed service. As the numbers are separate with each individual, these numbers are necessarily inlaid by a quick process. These smooth white disks with their black numerals are turned out in great quantities in a special factory under the supervision of the inventor. The curved plates for the caps are shaped on a curved bed plate in the toggle press. On a recent round the world trip, the inventor met his tags in every land and introduced himself in Alexandria, Egypt, by removing one from the cap of a porter and pointing to the firm name and address on the under side.

The Practical Use of Seaweed

SIX kinds of seaweed are used in the construction of Japanese isinglass, or agar-agar, the method of manufacture being described as follows in a recent U. S. Consular report: The seaweed is first crushed, each kind separately, to remove shells or other adhering matter, and then washed clean with water. The washed seaweed is placed on a mat and dried until its color becomes white by the action of the sun, frost, and dew. This operation takes place during September and October, and when bleached the weight of the seaweed is decreased nearly one-half. After bleaching, the six kinds of seaweed—in the proportion of Izu, 4; Egokusa, 4; Misaki, 3; Hirakusa, 3; Nanbu, 4; and Onikusa, 2—are all put together in a boiler and cooked for about 14 hours, until they have become soluble. The liquid is then strained through a sack and a box with a bamboo sieve on one side, from which it runs into a container. From the container the liquid is ladled into trays about 3½ feet long and 3 inches deep. After remaining in the trays about 12 hours these are placed on a low stand, and the isinglass is cut into strips 3 inches wide and 14 inches long, with a knife and ruler. These strips are then put into a long closed wooden box (the ends of which are 3 inches square, one end being open and one filled in with a wire sieve) and pushed through the sieve end in the form of long fine strips. The isinglass is then placed on a low stand, which is covered with a clean mat, and dried in the sun during the day and frozen during the night for two or three weeks during January and February, being watered at midnight.

The Laboratory

Some Suggestions for Home Experiment

Experiments With High-frequency Currents

By Philip Edelman

THERE is perhaps no one piece of apparatus so interesting as a high-frequency or Tesla coil. With it the laws of electricity are apparently violated. Thousands of volts are taken into the body with no unpleasant effects, lamps are lighted without connecting

Fig. 1.—The completed coil.

wires, insulators become conductors, and various other wonders are accomplished. There is no end to its wonders, and yet it is a comparatively simple piece of apparatus.

There are two general types of these coils, the oil-immersed and the open-air kind. For performing the following experiments the latter type will be described, as it is much simpler and accomplishes the same results.

The secondary of the coil is wound upon a paper or fiber tube 10½ inches in diameter and 10½ inches high. Beginning ½ inch from one end, wind 80 turns of No. 28 spring brass wire upon this tube. Wind this wire on very carefully, spacing each turn 3/32 of an inch apart. About 1/3 pound of wire will be needed. Give the finished secondary several coats of orange shellac, allowing each coat to dry before applying the next. The ends of the wire are fastened to the tube by punching two holes in it and sewing the wire into them.

For the primary winding, form 7½ feet of No. 4 rubber or weatherproof covered wire into two turns 13 inches in diameter and as near to a perfect circle as possible. The complete coil is shown in the photograph, Fig 1.

The accessory apparatus necessary are: a ¼, ½, or 1 kilowatt transformer or large spark coil, a large condenser, gap, etc. The transmitter of a wireless station will just about conform to these requirements. This Tesla coil will work to some extent even on a 1-inch spark coil. It gives a 3 to 5-inch spark on ¼ kilowatt, according to the adjustment.

Two methods of connecting the coils are shown in Fig. 2, an alternative form being given in Fig. 3. The success of the coil depends on the adjustment. You must have the right amount of capacity (condenser) and the right length of spark gage or you will get but poor results. You can only determine this by trial. After you have found the right proportions and the coil is sparking well, you are ready for the experiments.

Ground the lower terminal of the coil and close the switch controlling the spark coil or transformer. Now bring your hand near the top of the coil. These experiments are best done in the dark. Before you bring your hand near the coil, the top of the secondary glows with a beautiful corona brush. I have seen this done with a 15-kilowatt outfit. Snake-like twisting sparks shot out from the top. You may be able to see these on a small scale. As your hand approaches, a beautiful blue brush forms between it and the coil. The color intensifies until—"Ouch!" A spark jumps to your hand and stings you. Now hold a pair of pliers, screw-driver or any metal piece in your hand and repeat the

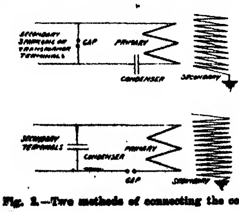


Fig. 2.—Two methods of connecting the coil.

experiment. This time the spark jumps to the metal and then into your body. If you are using less than ¼ kilowatt in the coil you will not feel any pain; ½ kilowatt will sting a little

You may wonder at this. You know that if this had been an ordinary spark at low frequency it would have been a terrible jolt, if nothing worse. Roughly counting 15,000 volts to the inch, you can readily calculate what you have just had through your body. But high-frequency currents, unlike low-frequency currents, travel on the outside of a conductor, and do not penetrate the inside The current travels on the outside of your body, and does not penetrate to your nerves. The sting you felt was caused by the heat

After you have become accustomed to taking this spark, grasp an incandescent light bulb in your hand, as shown in Fig. 3, and bring it to the top of the coil Sometimes in doing this the filament is jerked to pieces. An 8 candle-power lamp works best. The filament lights up Try the lamp on the middle and also near the bottom of the coil The lamp lights up brighter near the bottom than on top. There are numerous variations to this experiment For instance, two lights can be lighted, as shown in Fig 3.

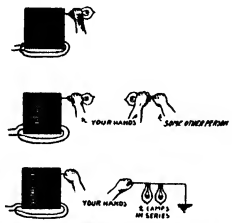

Fig. 3.—Lighting lamps without wires.

Now grasp a lamp by the bulb (it may be a burnt-out lamp) and allow the spark to jump to the capped end of the bulb. Little webs of sparks will form and the filament will dance around The filament may get red hot The bulb is now charged and if you put your other hand on the cap you will get a good shock. The bulb may be discharged to some one else, the ground or any conductive body.

Holding a burnt-out bulb by the cap, bring it near to the coil At first it lights up a pearl green. Next bring it very close for a second, allowing the spark to puncture the glass, when it will turn a pink color, and then of you continue a while longer it will turn a purple color. While it retains this purple color it is quite sensitive, and lights up if held in the hand a few feet away from the coil. These effects vary with every bulb used. Sometimes exceptional effects can be seen, while at other times nothing extraordinary happens.

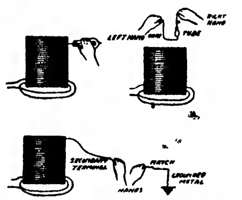

Fig. 4.—Experiments with burnt-out bulbs and lighting a match.

Geissler tubes held several feet away from the coil light up brilliantly. They are real wireless lights because there are no connecting wires. You can trace the lines of force to a slight extent by changing the direction and position of the tube and noticing the change in the brightness of the tube A strange effect is shown by Fig 4. Your hand and the tube form another secondary of the coil Besides the tube's lighting, little sparks pass from the hand to the tube If you vibrate the tube backward and forward rapidly, you can see little bands of light and shade.

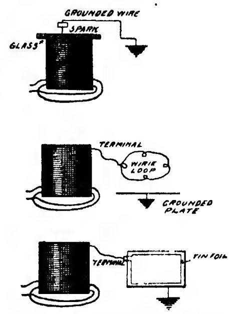

Fig. 5.—Curious brush discharges and illuminated signs.

You remember the burning sensation of your first spark To prove that this spark is very hot, you can light a match by it. It is best to use a pair of pliers for comfort You can burn wood, paper, light a candle and powder in this same way Try the experiment with these materials, as shown in Fig 4.

If a glass plate is laid on the coil as in Fig 5, the spark will seem to pass right through it. But the glass is not pierced, instead the spark is transferred to the other side of the glass by condenser action.

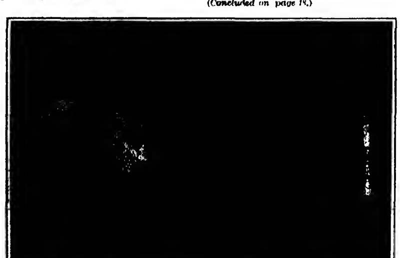
By forming loops of various shapes, as in Fig 5, you can get some very pretty brush discharges from your coil A name sign, Fig 5, is prepared by coating one side of a glass plate with tinfoil and the other side with the name, formed with fine wire A terminal of each side of the coil is connected to the plate and the name respectively.

Some Experiments With Blue Glass

By Prof. Gustave Michaud, Costa Rica State College

COMMON blue glass owes its color to the presence of cobalt It is transparent for the two extreme regions of the spectrum, red on one side, blue and violet on the other. It stops most of the central spectrum, i. e., orange, yellow and green From that point of view especially, it is altogether different from the yellow and red glasses used in photography and for which the absorption spectrum is unilateral That the cobalt glass allows the free passing of the extreme red is by no means evident at first sight, and it seems as if only pure blue light were admitted In the extremely simple experiment described here the red light admitted with the blue and violet is caused to stand away from both and thus becomes visible. This experiment is probably the only one in which an absorption spectrum can be distinctly perceived without prism, diffraction grating or apparatus of any kind

(Concluded on page 18.)



The eye used as a spectroscope.

Inventions New and Interesting

Simple Patent Law; Patent Office News; What Inventors Are Doing

A new gun for use on aeroplanes.

The Lewis Gun for Aeroplanes

By William Joseph Wheatley

WHEN an aeroplane soared aloft from the Army Aviation School at College Park, Md., the first part of June, carrying a new rapid-fire gun, the invention of Lieutenant-Colonel Isaac N. Lewis, of the United States Army Coast Artillery Corps, these machines left the realm of air scouts and from that time forward became active engines of war for both offensive and defensive work. The possibilities of the new gun were realized when the aeroplane came down after Capt. Charles deForest Chandler, commandant of the school, who manned the gun on its air trip, had discharged a full magazine of fifty cartridges, and an examination of the target had disclosed the fact that the forty-five shots fired had buried themselves in a space three yards by eighteen. The white target of cheesecloth measured three yards by fifteen, and while a number of shots had pierced the cheesecloth, the greater part were hunched just off the end. Five of the shots from the magazine had been sent into a fishpond on the reservation in order that Capt. Chandler could get, by the splash of the water, an instantaneous report of the accuracy of his aim.

The aeroplane, driven by Lieutenant Thomas DeW. Milling, one of the army aviators, was humming through the air at approximately fifty miles an hour, and at an altitude of 600 feet, when a ripping sound heard above the roar of the engine told that the gun was in action. Twice again the aviators flew over the target until the magazine had been exhausted. The fact that this was the first time the gun had been taken aloft together with the trueness of the aim as shown by the examination of the target spoke emphatically then and there of the great possibilities of fleets of aeroplanes loaded with these rapid-fire guns, soaring over a column of the enemy's troops.

No smoke, no flame—only the sound of the explosion tells that the gun has been fired. There is no recoil and the gun is so balanced by the magazine that the aim is not even interrupted while the gun is being fired. It can be fired at as high a rate as 750 shots a minute, but the rate may be reduced to 350 shots per minute, or to any number between those limits, by a simple adjustment of the gas-port valve controlling the admission of the gas to the piston cylinder.

The principal and most novel feature of the gun is its air-cooling system. The 30-caliber gun barrel is surrounded by a close-fitting aluminium jacket, cylindrical in form and having some twenty deeply-cut longitudinal grooves which extend from breech to muzzle. The gun barrel with its grooved jacket is inclosed in a light steel tube 3¾ inches in diameter, the portion of the tube which projects beyond the muzzle having a reduced diameter of only 2⅛ inches. The inclosed grooves, forming continuous air ducts in the aluminium jacket throughout its length, have free communication with the atmosphere at the breech and each time the gun is fired the ejector action of the discharge blast sucks in a draft of cool air from the rear through these ducts, thus carrying off the heat transmitted to the jacket from the barrel. The cooling is automatic in action, without the use of water or other cooling liquid and without mechanism or moving parts. As aluminium has six times the heat conductivity of steel and but one-third its weight, this very effective method of cooling the gun adds but a few pounds to the total weight carried. Another novel feature which differentiates the Lewis gun from all other gas-operated guns is the small inclosed operating spring which is located near the trigger-piece at the breech far removed from all injurious heat effects. The temper of this spring cannot be affected by either direct or transmitted heat no matter how rapid and long-continued the firing.

When firing at full speed it takes approximately four seconds to discharge a magazine of fifty cartridges, and the empty magazine may be replaced by a full one within two seconds. The drum magazine used with this gun is 8¼ inches in diameter and 1½ inches deep. It is stamped from sheet steel, has an aluminium center piece to hold the cartridges in place and resembles, somewhat, a reel used for winding cinematograph films.

Colonel Lewis designed the gun primarily for infantry and cavalry use, but its flameless feature coupled with the absence of recoil and its light weight brought to mind the possibilities of the rifle for aeroplane use, and a test was decided upon with the success already noted.

The development tests of the gun, which have been in progress for the past two years, show that the barrel does not become overheated under continuous fire at full speed, and that it will not therefore be necessary to carry along an extra barrel when on the firing line. Since no cooling water is necessary, and no special mount except a small stake or "cow-boy" mount weighing about eight pounds, the field equipment of the Lewis gun is reduced to a minimum. The gun may be fired from any natural support found in the field such as a rock, log, stump, tree or mound of earth. It is even possible to empty a magazine while holding the gun to the shoulder or from the hip, as the recoil effect is very slight.

It is a matter of note that one of the most conspicuous things on the battlefield in South Africa was the jet of steam from the boiling water which was being used on the barrels of the rapid-fire guns for cooling purposes.

Weighing as it does a little more than twenty-five pounds and requiring but one man to operate it, Colonel Lewis' invention has certainly made a great stride toward developing the aeroplane into a first-class ship of war.

The gun is simplicity in itself. It has only forty-seven parts, as compared with twice that number for other rapid-fire guns. On the battlefield or in the air where tools are necessarily scarce, and where they are needed more than anywhere else when they are wanted, Colonel Lewis' invention would certainly cause no worry, should some piece of the mechanism be broken or otherwise get out of working order, since the only tool required to disassemble or assemble the gun is the point of a bullet.

The sustained rapidity of fire of which the gun is capable makes it a far more dangerous and effective weapon than any bomb-dropping device as yet devised.

The men who tried the gun.

The gun in use from the ground.

As soon as a new machine is delivered to the Signal Corps to replace the flier which was wrecked recently, further and more complete firing tests of the Lewis gun will take place at College Park. It is proposed to carry the gun and one thousand rounds of service ammunition to heights of 1,000 feet or more and fire at selected targets to determine the accuracy of fire at different heights and speeds. The results of these firings will no doubt have far-reaching effect upon navy and coast defense plans for the future. However, with the results already obtained in view, it seems only a question of Congressional appropriation to decide whether or not we are to keep the lead in aeroplane armament.

Another question brought up in connection with the possibilities of this gun is its ability to attack the men on the decks and in the fighting tops of battleships. Battleships of the future, of course, will be equipped with hydro-aeroplanes for scouting purposes and even, possibly, to report the gun ranges of the enemy. Should these hydro-aeroplanes each be equipped with the Lewis rapid-fire gun they would play havoc with the range-finders telephones, lines of communication and the personnel in the fire-control masts such as those with which the battleships of the United States are equipped. It would mean that the men who direct the fire of their guns from these fighting tops will have to be protected. Some form of overhead protection will undoubtedly be necessary to protect the fire-control personnel, and naval officers of the various bureaus are, it is said, much exercised over the possible effects of attempting such protection.

The gun made a very successful demonstration of its possibilities as a service weapon for the mobile army at Fort Myer, Va., recently, before Secretary of War Stimson, Major-General Leonard Wood, Chief of the General Staff Corps; Brigadier-General William Crozier, Chief of the Army Bureau of Ordnance; Brigadier-General Erasmus M. Weaver, Chief of the Coast Artillery Corps; Brigadier-General E. A. Garlington, Inspector-General, and Brigadier-General E. H. Crowder, Judge-Advocate-General.

A $10,000 Prize for a Practical Sugar Beet Puller and Topper

THE Great Western Sugar Company of Denver, Colo., has offered a prize of $10,000 for a practical sugar beet puller and topper which shall fill the specifications given in a circular published by the company and which may be obtained free of charge on application to the company. From this circular we glean the more salient conditions as follows:

The beet puller and topper must fulfill the required specifications to the complete satisfaction of a committee of judges appointed by the company.

The offer may be in force until the first day of March, 1915, but the prize may be

awarded at any time prior to the first of March, 1915, when a practical beet puller and topper is forthcoming.

If two or more contestants fulfill all the required conditions and specifications, the committee of judges are to exercise their sole discretion and are to award the prize to the one who in their opinion has solved the problem most practically.

The contestants will be required to demonstrate their machines at such times and places as the committee of judges may designate. The contest is open to the general public including the employees of Great Western Sugar Company, and of all sugar companies.

The Great Western Sugar Company by awarding the prize will acquire no interest in the invention, design or machine of the successful contestant.

The motive power required for different soil and weather conditions must not be excessive, that is, it must not exceed four horses per beet row, if animal power is used. The device must pull and top all the beets and separate beets and tops, and leave the beets and tops convenient to load. It is especially understood that the work may be done by two machines, of which one does the topping, the other one the pulling or *vice versa*, although a combined machine is preferred. The pulling and topping must be done in a satisfactory manner. The beet puller and topper must be adjustable for rows spaced from sixteen to twenty inches apart. Damage to the beets or tops must be avoided as much as possible.

The selling price of the machine to the public by the local dealer, whether combined or otherwise, must not exceed $300 if the motive power is animal power and must not exceed $500 if belt-propelled.

Argental—A New White Metal

A Competitor of Silver.

A METAL or alloy, of very high-class qualities, has recently been evolved, after many years of research and experiments, by William A. McAdams. This new metal will be named "argental," because it is an alloy of silver and aluminium, the affinity of which is produced by chemicals and rare minerals, and it is par excellence as a substitute for silver having all its qualities except weight.

Argental has been produced to compete with silver, and for general manufacturing and industrial uses it is in many ways far superior to silver for the reason that, being alloyed with aluminium and cast by means of a patented compound and molds, or dies, it has many times greater strength than either silver or aluminum. It is white like silver and not leaden or blue like aluminium.

The silver in its composition prevents the aluminium from being attacked by ordinary alkalies, and the aluminium prevents the silver from being attacked by ordinary acids The alloy cannot be affected by nitric acid, and it will not tarnish or oxidize, by exposure to the atmosphere or gases. Its specific gravity is only one third that of silver, and consequently three or four times the quantity of manufactured articles can be produced from the same weight as that of silver, such as watch cases and movements, forks, spoons, bells, tableware, ornaments, hardware specialties, typewriters and similar machines, not mentioning a number of other incidental articles.

Comparing argental in weight with other metals, we find that it is one fourth the weight of copper, one fifth that of iron, one-fourth that of gold, and one sixth that of platinum.

The alloy can be cast, die-cast, rolled, spun, drawn into wire, milled, engine-turned, and turned in the best manner and the finest of threads cut on it. It takes a fine polish.

This metal is simply pure silver, alloyed with aluminium by means of chemicals and rare minerals. In the case of argental, the silver is alloyed with aluminium, in order to produce a neutral metal, which is proof against ordinary acids and alkalies, and also to gain great strength and lightness.

Notes for Inventors

A Bread Wrapping Machine.—In a recent issue of the SCIENTIFIC AMERICAN we stated that a machine was needed for wrapping bread in suitable paper. We are in receipt of a letter from the *National Baker*, of Philadelphia, informing us that such machines are well known.

A Packard Automobile Invention.—The Packard Motor Car Company as assignee of Russell Huff of Detroit, Mich., has issued patent No. 1,029,063, for a motor vehicle in which guards at the sides of the body extend to the rear of the body and a license plate is mounted on and directly above the rear extended part of one of said guards while a lamp is mounted on and directly above the extended part of the guard with one of its lenses facing the license plate so that the rays of light from the lamp will illuminate the license plate.

Two Hudson Maxim Patents.—Mr. Hudson Maxim has secured two patents, Nos. 1,028,472 and 1,028,473, for vessels of war. The vessel presented in the first patent has two oppositely disposed longitudinally extending water compartments for its immersion with inlets and outlets leading to the front and rear respectively and a propeller in proximity to the rear outlet; while the second patent is for a torpedo boat consisting of two hulls united longitudinally end to end with a war head carried by the forward hull and an auxiliary explosive head carried at the front of the war head.

A Machine that Demonstrates Varnishes.—In a patent, No. 1,029,223, issued to the Ohio Varnish Company of Cleveland, Ohio, as assignor of Walter R. Rae of Chicago, there is presented a demonstrating machine in which is combined means for automatically performing repeated cycles. These cycles include the application of the material such as varnish, the manipulation of such material, such for instance as to produce an effect illustrative of graining and then the automatic obliteration of the graining so that the apparatus can repeatedly produce to the eye the effects of the application and manipulation of the material in order to permit its use in advertising a particular material.

Rope Horseshoes.—An industry which might, it seems, be developed to advantage in this country, is that of rope horseshoes. These are largely used in Germany and some other foreign countries and should find favor here because of the large mileage of paved streets in most American cities. The rope portion is inserted in a metallic body or frame and in most instances provision is made for withdrawing a worn rope section and replacing it with a new one. In some instances the rope which is sometimes tarred has wire or other reinforcing material interwoven with it. Berlin is the headquarters of a syndicate composed of eight manufacturers located at different points of Germany. Possibly the practical development of the industry in this country would necessitate the modification of the shoe either in its metallic or rope portions or both to adapt it to local conditions.

Activities in Inventions. — Activities along certain lines of inventions result from various causes. Sometimes the demand creating the activity is local, at other times it is universal, while it is, at other times, produced by some peculiar condition calling for special results. Thus the large number of apartment houses has led to the activity in the class of automatic fire recorders for indicating the precise location of a fire within the area covered by the apparatus. Automatic telephones have experienced an impetus from the installation of phones in small series which do not warrant the expense of a "hello girl" exchange. Local conditions in California and Colorado, those great resorts for consumptives, have contributed largely to the insistent demands for antiseptic mouth pieces for telephone transmitters, many patents for such devices eventuating from applications filed from such States. This offers a field for invention which is practically as unlimited as that for individual drinking cups.

Legal Notes

Recent Adjudicated Patents.—Out of five adjudicated cases reported in the Patent Office Official *Gazette* of June 4th, 1912, only one patent was declared invalid. This was the design patent to Boldt, No. 39,921, for a bottle, and the U. S. Circuit Court of Appeals held this patent void on its face for lack of patentable novelty and invention. In the other four cases, three were held not infringed and one, the Truffault Re-issue patent, No. 12,437, for a shock absorber for vehicles, was held valid and infringed.

A Process After an Apparatus Interference.—In deciding *ex parte* Gold, Assistant Commissioner Billings referring to the question of *res adjudicata* said, "it is perfectly apparent that if the claims state merely the adjusting of the device so as to operate it in the way in which it was designed to be operated they are not separably patentable from the machine itself—in other words, that they are but different statements of the invention defined by the apparatus claims. It, therefore, follows that the judgment in the prior interference is a bar to the allowance of any claims the alleged method of which could be carried out by the apparatus in issue in that interference."

Securing Benefit of Foreign Application.—In the case of *ex parte* Barthels, Assistant Commissioner Billings has held that "Where an applicant claims the benefit of the filing of an application in a foreign country for the purpose of overcoming a reference, his affidavit, filed under the provisions of Rule 75, 'should be accompanied by a copy of the original foreign application, certified to by the Patent Office of the country in which it was filed, and if it is not in the English language, a sworn translation of the same or a translation made by the official translator of this office. If the application was not made by the inventor himself, applicant's affidavit should also state that the application in the foreign country was filed for his benefit and that such procedure is in accordance with the procedure in the foreign country.' "

Concealment of Invention.—Asst Com Tennant in the case of Quenzer v. Callis again indicates the danger of concealing an invention in the event of a contest arising as to priority. In this case the Board of Examiners in Chief held that in view of C's concealment of the invention, he had forfeited his right to a patent, and the Assistant Commissioner in affirming the decision of the Board quotes portions of the decision of the Court in the case of Warner v. Smith, 84 O G., 311, including the following: "Can one who has made an invention and who has locked it up in the secrets of his own exclusive knowledge and who produces it only when some rival inventor has entered the field be held to have acted in accordance with the policy of the law or with the spirit and purpose of the constitutional provision? Such action, or inaction, as we might more properly term it, not only contravenes the interests of the public, but also operates to injure the rival inventor who in the meantime enters the field of invention."

A Marconi Decision.—Mr. Chief Justice Shepard in the Court of Appeals of the District of Columbia has held that "When after the termination of an interference the losing party presented claims which were necessarily included in the scope of the decision in the interference and concluded thereby, it was the duty of the Commissioner to reject such claims."

The facts in this case are stated to be as follows:

"M filed two applications disclosing different species of the same invention; but in neither of them was the invention claimed broadly. After the declaration of the interference between the later application and an application of B, a patent was granted on the earlier application. The interference was decided in favor of B, and thereafter M sought to reissue the patent with claims broad enough to cover the devices disclosed in both of his applications. *Held*, that these claims were properly refused on the ground that M's right thereto was concluded by the decision in the interference."

RECENTLY PATENTED INVENTIONS

These columns are open to all patentees. The notices are inserted by special arrangement with the inventors Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN.

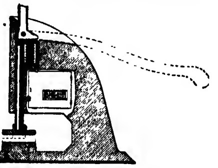
Of Interest to Farmers.

PLOW AND CHOPPER —C P BEAMES, Route 9, Carrollton, Ill The aim in this patent is to provide a machine especially designed for plowing up corn stubs and chopping the same with the stalks into small pieces or fragments, and scattering the same over the ground to be subsequently plowed in for fertilizing purposes.

COVER FOR PEACH BASKETS —I W. PECK, Bradentown, Fla This cover will prevent injury to the fruit from pressure, either external or internal, and by means of which the grower will be enabled to pack and ship his largest and finest fruit, and have the same arrive on the market uninjured by undue pressure from the cover or other crates stacked upon the crate in question.

Of General Interest.

REGISTERING SEAL PRESS – C D STAMPER, Williamsburg, Ky This invention has in view a press having associated therewith a register to indicate the number of impressions taken, the press and register being so combined as to secure simplicity of construction and insure the positive operation of the register, ac-



REGISTERING SEAL PRESS

cess to the latter being had only by the removal of a closure, ordinarily in the nature of a hinged door, which door is normally locked and sealed, and is to be opened only by the proper officer. The engraving shows a longitudinal vertical section through a registering seal press constructed in accordance with the invention

NON-REFILLABLE BOTTLE —W E GIROUD, 333 Decatur St, Brooklyn, N. Y, N Y Use is made in this invention of a valve mounted to travel in a spiral path in a valve casing, the valve having a spiral groove closed at its lower end when the valve is in lowermost position and is seated on the apertured bottom of the valve

NON-REFILLABLE BOTTLE

casing, the groove being open for the passage of the liquid at the time the bottle is tilted and the valve is off its seat The engraving of this improvement shows a sectional side elevation of the non-refillable bottle with the valve in closed position

GATE H C ANDERSON, R F D, Mount Vernon, Wash In the present patent the invention has for its object the provision of a single and cheaply constructed device, having means whereby it may be opened by persons on horseback or in vehicles without descending from the horse or the vehicle

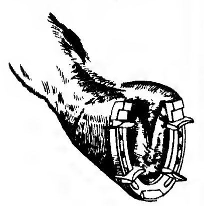
TORCH — J Z HANSON and R THORI, care of J Z HANSON, Aberdeen Idaho This invention relates to a torch particularly adapted for burning underwood or brush The torch is balanced to permit of ease in carrying the same, and a further object of the inventors is to provide a torch which will form a low forwardly-spreading flame in advance of the same

SPRING JOINT — W D TEUSTEN, 757 Macon St, Brooklyn, N Y, N Y This improvement relates to a form of spring joint that provides efficient means for housing the spring by which the joint is actuated, and the intention is to produce a superior joint which can be used in almost any relation where two parts are to be folded together

UMBRELLA - T SUSEMIHL and C P CARRINGTON, care of T SUSEMIHL, 1796 Fulton St, Brooklyn, N. Y, N. Y The more particular purpose here is to provide the umbrella with means whereby it may be disassembled and compacted into a small space and carried if desired in a small case for the purpose When spread

open and in active use, it assumes two distinct forms suitable for use under different weather conditions.

HORSESHOE.—A. M. H. De Bruycker, 173 Seventh Ave., Brooklyn, N. Y., N. Y. This inventor provides a horseshoe provided with detachable anti-slipping devices to permit the horse to obtain a sure foothold especially when going over icy roads, slippery pavements and the like. Use is made of anti-slipping calks ex-



HORSESHOE

tending transversely across the under side of the shoe and having upwardly-extending lugs engaging the outer and inner sides of the shoe, and transverse fastening pins extending through the said lugs and through the shoe to fasten the calks in place. The illustration pictures in perspective the shoe as applied to the hoof.

PASTEURIZING APPARATUS.—C. Paulsen, Copenhagen, Denmark. The characteristic feature of this invention consists in the very large heating surface employed in proportion to the size of the apparatus, and in the means provided for the good and thorough stirring which can take place, and lastly the ease with which the apparatus can be taken apart and cleaned.

NON-REFILLABLE BOTTLE.—L. Schaffert, 675 Knickerbocker Ave., Brooklyn, N. Y., N. Y. The inventor provides a bottle which cannot be refilled but will permit the ready efflux of liquid from the same. Another object is to provide a bottle in which it is difficult to obtain access to the means closing the same. And further to provide a bottle which cannot be opened by exhaust pressure.

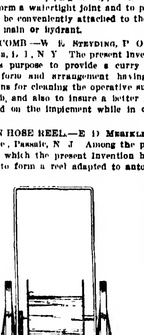
DEVICE FOR PREVENTING SPREAD OF EXPLOSIONS IN COAL MINES.—J. Cosavello, 1148 Penn Ave., Pittsburgh, Pa. In this patent the object of the inventor is to provide the chamber of a coal mine, in which coal is being dug, with a suitable device coöperating with the doors leading into the said chamber so that should an explosion occur in this chamber, the doors will be closed immediately.

Hardware and Tools.

HOSE LOCK.—O. V. Jackson, care of R. B. McCullough and R. L. Philips, Brunswick, Ga. In this invention the improvement relates to hose locks designed to unite the end of a hose to a section of piping or nipple in such a way as to form a watertight joint and to permit the hose to be conveniently attached to the end of a water main or hydrant.

CURRY COMB.—W. E. Steyding, P. O. Box 311, Mineola, L. I., N. Y. The present invention has for its purpose to provide a curry comb of simple form and arrangement having improved means for cleaning the operative surface of the comb, and also to insure a better grasp of the hand on the implement while in operation.

GARDEN HOSE REEL.—E. D. Meeikle, 308 Ayerigg Ave., Passaic, N. J. Among the principal objects which the present invention has in view are: to form a reel adapted to automati-



GARDEN HOSE REEL

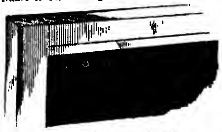
cally wind the hose as the reel is moved along the path of the same to avoid dragging the hose over the ground; to provide in a reel of the character set forth means for releasing the winding drum from the rotary mechanism therefor; and to provide means for holding the reel in upright position to serve as a sprinkling adjunct. The reel is shown in a front view in the illustration.

Heating and Lighting.

FURNACE FOR GAS GENERATORS.—F. J. Orr, 761 Prospect Ave., Buffalo, N. Y. This invention conserves the maximum units of heat by heating the walls and interior structure of the furnace to a radiating condition, which, after being raised to the necessary temperature, is there maintained by renewing the heat lost by radiation; and provides a conveyance of air and gas through the walls and structure of the furnace to produce the maximum affect.

Household Utilities.

FLY ESCAPE FOR SCREENS.—H. W. Welty, 416 E. 40th St., Chicago, Ill. The intention in this case is to provide a screen for doors and windows of buildings so constructed as to permit the escape from the building of such flies and other insects as may be upon the inside and yet effecinally prevent the entrance to the building of such flies and insects



FLY ESCAPE FOR SCREENS

as may be on the outside. The screen comprises a frame of the usual form and of any usual or preferred material. The accompanying illustration provides a perspective view of a portion of a door or window screen embodying the invention and looking at the outside thereof.

BRACKET.—W. Piplowski, 414 Bedford Ave., Brooklyn, N. Y. Among the principal objects which the invention has in view are: to provide brackets adapted for installation without marring the trim or finish of a door or window opening. It is to obviate a number of objections that the present brackets are provided with means for securing them to the trim different from that heretofore employed.

Machines and Mechanical Devices.

BELT SHIFTER.—E. J. Egan, Winchester, Ky. This invention has for its object the provision of a simple and positively operated mechanism for use in shifting a belt on stepped cone pulleys, wherein the shifting mechanism is supported on a traveling carriage, operated by a traveling cam.

DITCHING MACHINE.—N. W. Griesler and A. G. Griesler, R. F. D., 4, Van Wert, Ohio. The purpose here is the provision of a device which will remove the soil by layers, until the ditch is completed, and which will be entirely automatic in its action, and wherein a grinding means is provided for constraining the machine to follow the ditch.

MACHINE FOR PILING TEXTILE FABRICS.—C. J. Priester, 25 Bleecker St., New York, N. Y. Among other provisions this invention provides means for supporting and depositing devices, rods, or other retaining means for holding the fabric at each end of the lay performed by the machine, provides means wherein anchoring devices for holding the cloth at the ends of the lay are carried, and from which they are automatically fed; provides means for feeding cloth to a cutting table to prevent trapping the air between layers of cloth to disturb regularity of the lay; provides for guiding cloth from the piling machine to the lay, provides receptacles for the cloth-anchoring devices and adjustable means for feeding cloth therefrom when delivered in bolt or plied form.

FLEXIBLE COUPLING.—W. J. Francke, care of John Waldron Co., New Brunswick, N. J. In the present patent the improvement has reference to shaft couplings, and the purpose is to provide a new flexible coupling arranged to insure proper transmission of the power from one shaft to another even should such coupled shafts be out of line or out of center.

MACHINE FOR CUTTING SLICES OF BUTTERED BREAD AND SANDWICHES.—S. A. Gage, 13 Rue de Presbourg, Paris, France. This invention relates to a machine for the production either of slices of buttered bread or of sandwiches, the machine being so constructed that the two pieces of bread shall be of the same thickness and the slices of buttered bread or sandwiches, as the case may be, delivered in a continuous way.

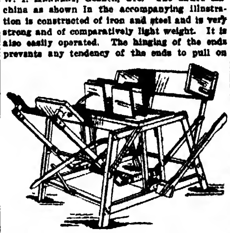
ROCK GATHERING AND EXCAVATING MACHINE.—D. A. Gilchrist, Belgrade, Mont. Draft animals may be attached to this machine, and it is constructed so that it may be operated automatically when advanced by the horses to pick up rocks lying at or near the surface of the earth. A special arrangement is made for adjusting the device to this work, and scoop attachments are provided for use to transform the machine into an excavator.

CENTRIFUGAL PUMP OR BLOWER.—M. Neumayer, care of W. C. Green, 506 Bell Block, Cincinnati, Ohio. This machine is simple in construction and rendered very effective in operation by the use of a special runner and a plurality of suction chambers, so that the fluid passes through the machine in stages with increasing velocity, finally leaving under a desired pressure and predetermined delivery capacity.

SAFETY FIRING ATTACHMENT FOR BREECH LOADING RIFLES.—F. Hartsuy, Field Hospital No. 2, Presidio of San Francisco, Cal. This invention relates to rifles for sea coast *defense* and mounted on disappearing carriages. The aim is to provide an attachment for breech-loading rifles, arranged to prevent firing of the loaded gun until the latter is raised in firing position, thus preventing premature discharge of the gun into the projecting parapet.

CLOTH LAYING MACHINE.—A. H. Van Devander and J. E. Moore, care of H. Van Devander, Cedartown, Ga. This machine will stack superposed layers of cloth in predetermined lengths in a smooth and even manner, with the least possible effort on the part of the operator. The machine can be used to lay different lengths of cloth and stack them by hand or power, in a pile on an adjustable cloth receiving member.

CEMENT BLOCK AND BRICK MACHINE.—W. I. Kennedy, Goshen, Ore. The entire machine as shown in the accompanying illustration is constructed of iron and steel and is very strong and of comparatively light weight. It is also easily operated. The hinging of the ends prevents any tendency of the ends to pull on

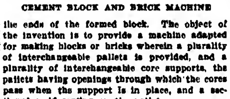


CEMENT BLOCK AND BRICK MACHINE

the ends of the formed block. The object of the invention is to provide a machine adapted for making blocks or bricks wherein a plurality of interchangeable pallets is provided, and a plurality of interchangeable core supports, the pallets having openings through which the cores pass when the support is in place, and a sectional mold resting on the pallet.

METHOD OF PERFORMING OPERATIONS INCIDENTAL TO MACHINE EMBROIDERY.—H. Bosshardt, 8a, 955 Hill St., Hoboken, N. J. This invention relates particularly to a method of forming a combined color filled and embroidered fabric where figures are stenciled on the fabric instead of forming said figures by means of color covering or leaf stitch and more particularly to a method of pantographically forming a duplication of the figures on a pattern blank and in forming outlining stitches bounding said figures after they are stenciled on the fabric.

CENTERING DEVICE.—F. L. Wheeling and F. A. Rogers, 746 Lake St., Los Angeles, Cal. This device is for use on lathes and similar machines, and more especially for centering "offset" work such as crank and cam shafts, valve eccentrics, etc., arranged for keeping the work in one center while one or more cranks or cams are being turned. For this purpose, use is made of a face plate attached to and



CENTERING DEVICE

rotating with the head stock spindle of the lathe, a tail stock face plate mounted to rotate on the tail stock spindle, and work-carrying means adjusted laterally on the said face plates, for supporting the ends of the work eccentrically to the axis of the spindles. The engraving shows a rear view of part of the lathe with the centering device, and showing a crank shaft for turning the cranks thereof.

WORD COUNTING ATTACHMENT FOR TYPEWRITERS AND TYPESETTING MACHINES.—E. F. Goin, Nardin, Okla. This inventor has in view a compact registering appliance applicable to any typewriting or typesetting machine, and readily thrown into and out of operation, as well as reset, by depressible keys. Thus the working of the counting device can be carried on the same as if it formed a part of the key-operated mechanism of the machines.

Prime Movers and Their Accessories.

INTERNAL COMBUSTION ENGINE.—Dr. R. H. Powell, Grafton, W. Va. The objects here are to provide a device by means of which the scavenging of the engine may be effectively accomplished; a device in which a higher compression is secured; a means for cooling the piston and the cylinder; a device in which the carbon deposit on the piston and cylinder is reduced to a minimum, due to complete combustion; and a device capable of using a longer stroke.

Railways and Their Accessories.

BRAKE SHOE ADJUSTER.—[illegible] worth, Box 124, [illegible] This invention has for its purpose to provide a simple apparatus which may be used on car trucks either with outside or inside brake beams for automatically adjusting the position of the brake shoes relatively to the wheel, to take up the slack caused by wear.

RAILWAY SWITCH.—C. E. [illegible], Livingstonville, N. Y. This positively-acting device is operable from the street car, the switch being thrown by the motorman to either of its positions by depression of an operating member carried by the car, the member in each instance at either side of the switch working one of the two aligning operating cams as the car passes thereover, which cams are rapidly connected and ordinarily arranged between the rails, one of these cams being thrown up to operative position when the other is depressed to throw the switch.

Pertaining to Recreation.

BUBBLE BLOWER.—F. H. Coustrueren, 88 Greenpoint Ave., Woodside, L. I., N. Y. This inventor provides an apparatus the operation whereof results in the formation of a plurality of soap bubbles, one contained within the other; and provides means contained within the apparatus for insuring the formation of the bubbles in the prescribed manner and correlation.

Pertaining to Vehicles.

RESILIENT VEHICLE WHEEL.—H. J. Sheedy, care of J. E. Schlager, Stewart Packing Co., Scranton, Pa. This wheel has a hub and a rib member spaced therefrom and disposed thereabround, there being recesses in the hub and in the rib member for receiving projections on pneumatic members, which are disposed between these members, the pneumatic being reinforced by rods having threaded terminals projecting through terminals of the pneumatic members, and which are engaged by nuts pressing the terminals of the pneumatic members against shoulders on the rods, the nuts engaging neighboring nuts.

SPRING TIRE FOR VEHICLES.—S. B. Crews, Tampa, Fla. This invention has for its object the provision of a practical, efficient, and durable spring tire for autos and other motor vehicles in which metallic springs are substituted for pneumatic pressure. The invention applies a punctureless tire having the same elastic quality as the more expensive pneumatic tires now generally used.

PUMP FOR AUTOMOBILE ALARMS.—W. H. Garlock, P. O. Box 686, Seattle, Wash. This device is for use in compressing air to sound an alarm. It is capable of being operated by hand or foot of the driver, and may be applied to vehicles of any construction without change in the vehicle itself, and wherein the operative parts are thoroughly protected from weather and external violence.

Prime Movers and Their Accessories.

OSCILLATING VALVE.—J. W. Davis, care of C. G. Hall, Box 349, Whitefish, Mont. This invention relates particularly to oscillating valves for locomotives, and to means for permitting the engine to run free when the valve is shut off. It automatically connects the intake and exhaust ports of the cylinder when steam is shut off so that the piston may freely move without creating any back pressure.

ROTARY PUMP.—R. H. Danner, 414 E. 64th St., Los Angeles, Cal. The object here is to provide a new and improved rotary pump, more especially designed for use in bored or driven wells, and arranged to prevent the bearings of the pump shaft from being cut by sand or other extraneous matter.

Designs.

DESIGN FOR A BADGE.—Mary F. Slattery, care of Mr. Cowan, 1418 Fifth Ave., Manhattan, N. Y., N. Y. This ornamental design embodies the Irish emblem of the shamrock and the snake, the animal lying obliquely across the stem and partly on the two lower leaves.

Note.—Copies of any of these patents will be furnished by the Scientific American for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

Kindly keep your queries on separate sheets of paper when corresponding about such matters as patents, subscriptions, books, etc. This will greatly facilitate answering your questions, as in many cases they have to be referred to experts. The full name and address should be given on every sheet. No attention will be paid to unsigned queries. Full hints to correspondents are printed from time to time and will be mailed on request.

(12655) "A Reader for Ten Years" has asked us as to the most modern method of making gelatine sheets, and what machinery to use, etc. We must emphasize the fact that we do not answer anonymous communications. All letters must contain full name and address of writers.

(12656) T. S. S. asks: Has there ever been any way discovered to make rain by artificial action? A. There is no proof that any rain has been produced artificially, or when rain would not have fallen by natural causes. The U. S. Weather Bureau has many times said this. It is very unlikely that any shock can be given to the air by exploding powder to cause the condensation of moisture to rain, since thousands of cubic miles are involved in even a moderate storm. This topic is treated in Milham's "Meteorology," a new book, which we send for $4.50.

(12657) We very frequently receive the question, "Is the Mississippi River higher at its mouth than it is at its source?" A correspondent recently criticised our saying that the river is farther from the center of the earth at its mouth than it is at its source, and also that it ran down hill all the way from its source to its mouth; that is, the source is higher above a water level than is its mouth. Both of these statements are true, and we propose to discuss the matter more fully. There are two points involved in the question: the figure of the earth, and the relation of the river at points along its course to the level of the sea. First, the figure of the earth. Those who would read a *résumé* of this subject will find a clear statement given in the Encyclopedia Britannica, eleventh edition, vol. 8, pages 801-813. The figure of the earth is defined as "the surface of the sea imagined to percolate the continents by canals." It is therefore a water-covered surface along what is called the sea-level. Mathematically it is an ellipsoid of rotation, as shown by Laplace in his "Mecanique Celeste," and, in English, by Sir George Airy in "Mathematical Tracts," and many others, among whom we will name Sir George H. Darwin, the son of Charles Darwin, and not less illustrious in mathematics than his father in biology. The generating ellipse is rotated upon the polar axis of the earth, which is also the minor axis of the ellipse. To determine this ellipse numerous measurements of arcs of meridians have been made in various parts of the earth, from the equator to Hammefest beyond the Arctic Circle. The results are discussed by A. R. Clarke in the "Comparisons of the Standards of Length" in 1866, and in his "Geodesy" in 1880. The conclusions reached are that the equatorial semi-diameter of the earth is 20,926,202 feet, and the polar semi-diameter is 20,854,895 feet. These are the dimensions of the earth employed by astronomers and geodesists in their computations, and they may be relied upon as having but a slight probable error. It is thus seen that the equatorial semi-diameter is longer than the polar by 71,307 feet, or 13.504 miles very nearly. It is upon this that the statement usually made is based that the equator is 13 miles farther from the center of the earth than are the poles. And thus it is that a river running toward the equator in either hemisphere is rising farther and farther from the center of the earth as it flows over the surface of the earth. We referred this question to the U. S. Coast and Geodetic Survey and received from them the following data: "The distances from the center of the earth to points on the spheroid (that is, the average sea-level surface of the earth), using approximate latitudes, are as follows. Mouth of the Mississippi River, lat. 29 deg. 00 min., 6,373,159 meters. Source of the Mississippi River, lat. 47 deg. 10 min., 6,366,524 meters." Reducing the difference between these two numbers to miles, we find that the mouth of the Mississippi River is 4.12 miles farther from the center of the earth than is its source. Doubtless most of our readers understand that this figure of the earth has resulted from the centrifugal force of its rotation upon its axis, while yet plastic in its early history, producing the equatorial ring about 13.5 miles deep. Along this surface water will not flow. It is the water level of the ocean. If the source of the Mississippi River were 4.12 miles nearer the center of the earth than its mouth is, there would be no flow of water in its bed from the source to the Gulf. We may also point out that it is along this water-level surface that a ship sails on the ocean. If a ship could sail from the pole to the equator, it would at the end of the voyage be 13.5 miles farther from the center of the earth than when it started from the pole; and yet it would have sailed along a water-level surface all the way. A ship does not sail up hill in sailing [illegible] miles up hill in running from Lake Itasca to the Gulf of Mexico. It is raised to that height by the earth's rotational velocity. This brings us to the second point in the question, the altitudes of the river at various places along its course. "Higher" of course refers to altitudes above sea level. Here we have recourse to the excellent "Dictionary of Altitudes," compiled by the U. S. Geological Survey, fourth edition, 1906, and give the heights of extreme low and high water for several places, with the dates when these heights occurred:

Place.	Low, feet.	Year.	High, feet.	Year.
New Orleans, La.	1	1888	15	1882
Red River, La....	6	1872	52	1882
Vicksburg, Miss...	42	1872	94	1884
St. Louis, Mo ...	379	1844	414	1888
St. Paul, Minn ..	683	1878	702	1881

Lake Itasca, Minn., altitude 1,664 feet.

If we take the figures for extreme low water, it is evident that the Mississippi River falls 1 foot in the 106 miles from that city to the Passes at its mouth; and that it falls 6 feet in the 310 miles from the Red River to its mouth; and that its total fall from the source to the Gulf is 1,664 feet. As we said in our former answer to Query 12618 to which exception was taken, "The Mississippi River flows down hill all the way from the source to its mouth, which means that the source is higher above a water level (which is sea level) than the mouth is. Water does not anywhere on the earth run up hill [except under pressure in closed channels] nor along a water level. It can only run from a higher level to a lower level."

(12658) G. P. G. asks: Suppose that we have two electrical resistances, equal when hot, and in series, so that they will each absorb the same amount of energy. Let one resistance take the form of say a tungsten lamp, so that it will emit the largest possible amount of light. Let the other resistance be composed of such a length and thickness of say iron wire that it will be only black hot. Here we have two resistances each transforming the same amount of electrical energy, the first into light and heat and the second into heat only. Query Will the number of thermal units liberated be the same in each case?—a thermal unit being that amount of heat necessary to raise 1 pound of water 1 deg. Cent. If you answer "Yes," it is evident that we get the light for nothing, which is not thinkable, and I would ask, is there any theoretical limit to the amount of light that may be produced from a given number of watts? A. We must answer your question that the heat generated is the same when the current and resistance in two circuits of the same metal are the same, for the same length of time. The formula is

$$\text{Calories} = 0.24\ C^2Rt \text{ in seconds.}$$

That a part of this radiated energy is of a short wave length which can affect the eye as light when it happens to enter an eye, but the rest is of such long waves that it only affects us as heat and does not affect the sum total of energy radiated at all. Heat and light are not two energies, but one appreciated by different senses. The same waves which affect the retina as light would, if they impinged upon the skin, affect the nerves by which the sensation of warmth is produced. The energy is not light till it affects the optic nerve, nor heat till it is perceived by the proper sense. It is not a case of getting anything for nothing. We get so much radiant energy That portion which we use as light we do not use as heat, and *vice versa*. We know no theoretical limit to the watt value of a candle. The arc lamp produces a candle for the least electrical energy. What can be done to reduce this cost we cannot say.

(12659) C. V. H. asks: In your number of April 27th you stated that any object which does not float at the surface will not float at any depth. What is, then, the reason that divers use lead boots and other weights in order to sink and keep their balance in underwater wrecking operations? A. Divers use lead weights upon their feet to sink them, because otherwise they would float and not sink at all. The air within their rubber suits would prevent them from going down. The weights are heavy because they need to push and work at the bottom, and unless they have a heavy weight they would have no power to do any work, but would be moved about by the slightest pressure against any object. They could not even walk about The weights on their feet are much greater than are required to sink them.

(12660) W. C. R. says: I observe that in the case of the "Titanic," as of other steamers that have foundered, it is stated that when the vessel sank the boiler exploded. I can understand that a mass of water rushing in upon the fire would create a vast amount of free steam, but should that have to do with pressure in the boilers, which one would expect to be lessened with the extinguishment of the fire? A. The sudden entry of water into the furnaces would generate large quantities of steam, which would rush up the uptakes and smokestacks. This and the roar of the escaping steam might lead to the belief that the boilers had exploded. The cold water would tend to condense the steam in the boilers and reduce the pressure.

(12661) W. H. J. asks: To what depths have divers gone? A. The "Encyclopedia Britannica," vol. 8, page 329, states that the greatest depth at which useful work has been done is 182 feet. A Spanish diver recovered silver from a wreck at this depth. Sponge fishers dive to a maximum depth of 150 feet, and the pearl fishers go to about 120 feet. The SCIENTIFIC AMERICAN, vol. 106, No. 22, gives the account of a submarine going to a depth of 300 feet.

NEW BOOKS, ETC.

THE NEW NAVY OF THE UNITED STATES. By N. N. Stebbins. Introduction by the Admiral of the Navy, George Dewey, U. S. N. 150 half-tone illustrations. New York: Outing Publishing Company. Price, $1.50.

Printed descriptions can do much in describing a warship, but a photograph or a drawing can do much more. It was with this conviction that the author of the present excellent work, who is a marine photographer by profession, has gathered together a series of photographs taken during the past twenty years by himself of the ships of our new navy. The author, whose studio is in Boston, was particularly well situated for the task, for the reason that of late years most of the trials for speed of our warships have been carried on at Rockland, Maine, and Mr. Stebbins has made a point of being present and taking photographs of the ships on their full-speed trials, whenever it was possible. In the early pages are to be found some excellent views of the older ships of the navy, including the "Constitution" of 1797, the "New Hampshire" of 1817, and the "Hartford" of 1858. The new navy dates from the early eighties, and the photographs include some excellent views of the ships of the celebrated "White Squadron," such as the "Boston," "Atlanta," and "Chicago." The later ships follow pretty much in the order of their construction, and the last views include such late ships as the "Florida" and "Utah." Also there will be found reproductions of wash drawings of the battleships "New York" and "Texas" and "Wyoming" and "Arkansas" now under construction, and a deck plan of the "Nevada" and the "Oklahoma." The list of views includes the colliers, the converted yachts, and the cutters of the Revenue Service Capt H. Uberoth's article on the Revenue Cutter Service is one of the most attractive features of the work.

EFFICIENCY AS A BASIS FOR OPERATION AND WAGES. By Harrington Emerson. New York: The Engineering Magazine, 1912. 12mo.; 254 pp. Price, $2.

THE TWELVE PRINCIPLES OF EFFICIENCY. By Harrington Emerson. New York: The Engineering Magazine, 1912. 12mo.; 423 pp. Price, $2.

If American industry, judged by easily attainable standards, is only thirty per cent efficient, then the sooner American industry awakes to the situation, the better for all concerned. Are we wasting nearly seventy per cent of our time, energy, and money? Could a few changes in industrial administration abolish the bread line and the necessity for feeding seven hundred starving children at the East Side schools, and incidentally place the United States in a position where she need not rely upon her exceptional but failing resources for commercial pre-eminence? Eliminate this seventy per cent of waste, says Mr. Emerson, and men may work less laboriously, receive higher wages, and deliver a better and cheaper product The works exhibit a masterly command of facts and illustrations They are broad and humane without being vague, keen and precise without being narrow, and they compel the most serious consideration When manufacturing plants, railway repair shops, and building operations are shown by reliable statistics to be carried on in so wasteful a way, certainly the remedy offered should be thoughtfully studied. It is not an untried experiment, but a plan that has already spelled success in many instances Briefly, it is to furnish the old-line organization with standards, and to supplement it with staff organization The line should no more resent this aid than—as Mr Emerson has it in one of his happy illustrations—the commander of a submarine resents the squeaking of the mouse that warns him of the presence of dangerous gases. The author proceeds to show the application of staff and standards to a typical shop Five surveys are run to determine the condition of machines and tools; the relation between what men are actually doing and what they should do; the relation between current costs and standard costs, the speed of movement of work through the shop, and the degree of efficiency in handling and checking materials The old method of finding costs after completion of the work, is superseded by the new method of anticipating them; in fact, predetermination of results is the main characteristic of the new method on the cost accounting side It is claimed that "the efficiency system" has resulted in reducing locomotive repair cost from eight cents, ten cents, and even twelve cents per mile to six cents, and that in other activities the reduction in expense has been as sweeping and extraordinary In "The Twelve Principles of Efficiency" the system is further amplified and expounded, and its claims substantiated by citations of actual accomplishments. In short, we must characterise these as two remarkable books whose every word is worthy of careful study and whose tenets demand the most careful test.

SOAP BUBBLES. Their Colors and the Forces Which Mold Them. By C. V. Boys, F.R.S. New York: E. S. Gorham, 1912. 16mo., 190 pp.; illustrated. Price, 85 cents.

"Soap Bubbles" is a series of most fascinating experiments bearing upon the elastic skin of liquids, capillary attraction, the tension and curvature of soap-films, and the color, thickness, and possibilities of soap bubbles The substance of the book was originally delivered in the shape of popular lectures before juvenile audiences, and serves admirably to awaken the youthful mind to the marvels of natural phenomena, and to incite it to further and more serious study.

CONSTRUCTING CONCRETE PORCHES. By A. A. Houghton. New York: The Norman W. Henley Publishing Company, 1912. 59 pp.

CONCRETE BRIDGES, CULVERTS, AND SEWERS. By A. A. Houghton, 132 Nassau Street, New York: The Norman W. Henley Publishing Company, 1912. 55 pp.

These two books may be commended for their clear, concise discussion of important phases of concrete construction

TEXT-BOOK OF PHYSICS. By C. E. Lineberger. Boston: D. C. Heath & Co., 1911. 12mo.; 471 pp.; illustrated.

As an elementary text, written for the average student, appeal is first made to any knowledge of the topic which the average student may be expected to possess, definitions are as crystallized as it is possible to make them, what little apparatus is used is carefully set forth in explanation and illustration, principles are concretely applied, and problems of moderate difficulty, calling for constructive reasoning, are furnished in abundance The arrangement of material is sound, and its variety and attractiveness commendable

METEOROLOGY. A Textbook on the Weather, the Causes of its Changes, and Weather Forecasting, for the Student and General Reader. By Willis Isbister Milham, Ph.D, Field Professor of Astronomy in Williams College. New York: The Macmillan Company, 1912. 8vo., xvi, 549 pp.; illustrated. Price, $4.50.

Meteorology has had a long struggle for recognition as a suitable subject for the university curriculum in this country Why this is so it would be difficult to say, in view of the fact that weather is a subject of universal interest. However, the anomaly of the situation appears to have been brought to the attention of academic authorities, and within a few years past courses in meteorology have been introduced at a score or more of our institutions of higher education A suitable textbook for these courses was an urgent desideratum, which Prof Milham has happily supplied in the treatise under review. Since the publication of Prof Loomis' now antiquated, but still highly useful, "Treatise on Meteorology," no work on this subject has appeared in the English language at all approaching Prof Milham's book in its availability for use in the college classroom Let us hope that some one will soon supply the equally pressing want of a textbook for high schools to replace the obsolescent elementary treatises of Davis and Waldo.

As a textbook, Milham's book may be compared with the second, condensed edition of Hann's "Lehrbuch der Meteorologie," than which it is more comprehensive, but less thorough Thus, Milham covers several important topics that Hann completely ignores, e g , meteorological instruments, weather prediction, and atmospheric optics On the other hand, for rigorously scientific explanations of atmospheric phenomena in the light of modern investigations, Milham's treatise can by no means be accepted as a substitute for the great German authority, and the teacher who uses Milham's textbook in his classes will need to have at hand both editions of Hann for constant reference On the descriptive side, Milham is adequate, but on the theoretical side rather superficial, and sometimes inexact.

For the general reader, Milham's book may be recommended as a compact body of up-to-date information It is especially to be commended for its cosmopolitan outlook. As a rule, an American work on meteorology is apt to be too American, and an English work too English, but Milham has drawn his information from all available sources, and especially from the rich storehouse of German science.

As to make-up, each chapter begins with a useful syllabus of its contents, and closes with collections of questions on the text, topics for investigation, practical exercises, and references; all of which is in accord with the best pedagogic practice The appendix contains a copious classified bibliography Charts, pictures, and diagrams are numerous and generally excellent, though the charts would have been more instructive if coloring had been more generously used. This is a point in which American textbooks suffer in comparison with German

This book has one serious blemish, which we feel it our ungrateful duty to point out—in the spelling of foreign words and names, with which the book naturally abounds, flagrant errors occur by the score We must hold the author responsible for the bungling of personal names with which the publishers' staff could hardly be expected to be familiar, as "Dové" for "Dove", "Mühy" for "Mühry", "Fisher" for "Fischer", "Lemstron" for "Lemström", "Edward Buckner" for "Eduard Brückner", etc.; but author and publisher are jointly to blame for the numerous egregious blunders in the spelling of everyday French and German words entering into the titles of the works listed in the bibliographies, such as "Erganzungscheft" for "Ergänzungsheft", "atmospherische" for "atmosphärische"; "practique" for "pratique", etc The number of such errors in the otherwise excellent bibliographies is truly appalling.

V.—Shall My Boy Become a Chemical Engineer?

By M. C. Whitaker, Professor of Engineering Chemistry, School of Chemistry, Columbia University

[This is the fifth of a series of articles intended to set forth fairly the business possibilities of the technical professions. The articles are prepared by men who are connected with the more important technological institutions of this country and who are for the most part prominent educators. Because these teachers have instructed hundreds of young men in the principles of engineering, they are best qualified to write upon a subject so immensely important in the future development of American manufacturing industries.—EDITOR.]

THE industrial progress of a nation depends primarily upon the skill and inventive talents of a certain portion of its population. The natural resources of a country may be exploited by a foreign people, but the national benefits from a true industrial growth can come only from native initiative. Industrial wealth increases as a result of research and discovery, and all developments not based on solid scientific knowledge are unstable and soon become undermined.

The first requisite for permanent industrial growth, therefore, is a class of leaders of thorough scientific training combined with a natural or acquired talent for developing applications. Advancement in the science and the art of mining, railroading, electrical applications and mechanical developments is necessarily solely dependent upon such a body of men. The more thorough and complete the training, the greater will be the facility with which they handle the inevitable new problems arising in their work, and the greater will be their contribution to the profession of engineering, and to permanent industrial development.

Schools of mechanical engineering have for forty years met the demands for men to develop the innumerable applications of mechanical principles and physical laws, and the graduates of these schools are engaged all over the country in designing, building and operating appliances for the utilization of power and the transformation and application of energy. The effect of their work may be seen in the development of the multiple expansion steam engine, gas engine, steam turbine, transportation machinery and innumerable other mechanical applications.

The education of men for the applications of electrical energy has kept pace with the development of the dynamo, the motor, the telephone and the telegraph, wireless telegraphy, etc. Our railroads, buildings, bridges and municipal works are directed and developed by the products of numerous schools of civil engineering. No one would question the wisdom of the establishment of schools to provide the training for these engineers. The scientific and industrial development in their respective fields has amply justified the existence of such schools and the demands for their graduates are constantly increasing.

There still exists, however, a branch of engineering, the scope and possibilities of which are greater than all of the others combined, and that is the field of manufacture involving the principles of chemistry. The value of the chemical products manufactured in the United States during the last year aggregated over $8,000,000,000. The development of the men to build up, manage and operate the numerous units going to make up this great industrial division has, until recently, been largely a hit and miss matter.

Who is best equipped to design, build and operate our factories and processes founded on chemical principles? Certainly not the electrical engineer, educated to work around the pivotal point of electrical theory and with little or no knowledge of chemistry. Certainly not the mechanical engineer, specially trained in the development, use and application of power and energy; nor the civil engineer, educated in the theory and practice of construction; nor the mining engineer, educated to win the raw materials from the earth. Among the classes enumerated, we find only those who are specialized in the recovery of raw materials and those trained to make applications of the finished products. The intermediate step—that of manufacture—has been entirely omitted. Our failure to recognize the need and to provide men trained in the application of engineering methods to chemical problems is amply illustrated by reference to the history of a number of our noted developments. The chemistry of the Solvay soda process was available for thirty-five years before the engineering difficulties were solved. Our present water gas system lay dormant for fifteen years before engineering talent could make it commercially successful. The principles on which the wonderful contact process for sulphuric acid is now operating, were well known to the chemist for many years before the indispensable chemist-engineers were found to solve the large scale applications. The electro-chemical principles published by Faraday lay fifty years awaiting the development of the mechanical and electrical appliances needed to perform the chemical functions. The European monopoly of the world's supply of sulphur was broken by a man who had the courage and skill to engineer well-known physical and chemical principles and thus create a new American industry.

In the other engineering branches there is usually a prompt application of newly discovered principles, but in the chemical field there is often a long delay between the publication of a new idea and its successful industrial application. Innumerable illustrations might be cited to show the lack of correlation between the science of chemistry and modern engineering development. If the principles followed in the training of mining, civil, mechanical and electrical engineers are correct, and their results seem to justify this conclusion, the field of chemical manufacture has been sadly neglected, and the difficulties experienced in the upbuilding of many of our now successful processes have been due to a scarcity of men trained in the special field of chemical engineering.

Other engineering developments are already being hampered by unsolved chemical problems. Some of these problems remain unsolved from lack of knowledge, some from lack of resources to pursue the necessary investigations on an illuminating scale, and others from the failure to centralize engineering resources around the focal chemical point. Railroad engineers are demanding improvements in the chemical composition and manufacture of steel to reduce the number of catastrophes occasioned by the rapid increase in the speed and weight of trains. Disintegration of structural materials like cement and steel are hampering engineering development, and chemical manufacture itself is handicapped by a lack of refractory metals and materials. Fuel problems, food problems, illumination problems, problems involving the conservation of life and property, are becoming more pressing as a result of the advance of general engineering. In almost every one of these difficult and important problems, the solution will come through a better knowledge of chemistry and its applications.

Some of our leading institutions are fully alive to the importance of chemical engineering as a profession and are providing excellent courses of training both in the fundamental sciences and also in the study of the applications. These chemical engineering courses require new and expensive laboratory equipment quite different in kind from that heretofore used in engineering school instruction, and infinitely more varied in its scope. The development of great laboratories of engineering chemistry will naturally offer the best facilities for the investigation of great industrial problems. In such schools, men with a knowledge of the theoretical sciences may be taught the best applications known to the combined engineering profession.

INQUIRY COLUMN

Inquiry No. 9264.—Wanted, the name and address of manufacturers of Gate Fitting Machines.

Inquiry No. 9265.—Wanted, names and addresses of manufacturers of machinery for making picket fences.

Inquiry No. 9266.—Wanted, to buy machinery for fastening wire cloth to wooden frames with coppered tacks.

Inquiry No. 9267.—Wanted addresses of manufacturers of metal specialties in connection with plate or window glass.

Inquiry No. 9273.—Wanted, to buy a globe for a parlor fountain, working on the Hason system.

Inquiry No. 9274.—Wanted, the name of a manufacturer of a machine to make cushion covers for [illegible].

Inquiry No. 9275.—Wanted, name and address of manufacturer of stock patterns of platen job printing presses.

Inquiry No. 9276. Wanted a household convenience and necessity which can be retailed at a profit at a price of from $1.00 to $2.00.

Inquiry No. 9277. Wanted. A machine for [illegible] dry [illegible].

Inquiry No. 9278. Wanted. A machine for [illegible]

Inquiry No. [illegible]. Wanted. A machine for [illegible]

The Annual Convention of the Master Car Builders' Association

By Reginald Gordon

THE annual convention of the Master Car Builders' Association was held at Atlantic City, N. J., June 12th to 14th, inclusive. The deliberations of this body of practical railroad men are always productive of matter of great value to the transportation world, especially in this day of large, heavy, steel cars, increasing rate of wages and always closer supervision by State and national commissions. There is a marked tendency among the various technical, railway and manufacturers' associations, of which there are many now in existence, to work together in the investigation and solution of the new and increasingly complex problems that arise from time to time in the economical operation and maintenance of railways. A large proportion of the membership of these societies is composed of technically educated men, whose opinions and decisions on questions relating to their respective departments of a railroad are of great value, involving, as they do, the expenditure of millions of dollars annually for labor, new materials and supplies.

After the address by the president of the M. C. B. Association, reviewing the work done during the past year, and the general progress made in car construction, the convention listened to a report upon specifications for cast and rolled steel wheels for cars. The experience gained during the past few years with the wheels used on 50-ton capacity coal and ore cars has shown the necessity of establishing rigid specifications governing the chemical composition, method of manufacture and mode of testing of steel wheels intended for that kind of service. While the majority of wheels in use under freight cars are of chilled cast iron, a kind of wheel that has given years of satisfactory service in the United States and Canada, many railroad men now distrust its margin of safety under modern conditions with heavy loads, which in the case of a loaded car means a weight of 37,000 pounds carried on every one of the four axles. The effect of bad track, the brittleness of the material at the low temperatures that are common above the 40-degree parallel of latitude, and the excessive heating caused by the brake shoes applied to the wheels on long descending grades, require a wheel that is very strong, hard and tough in its characteristics. The steel wheel costs more than that of chilled cast iron at first, but its dependable period of service is longer. Nevertheless, there were many members at the meeting who advocated the continued use of cast iron wheels, having found them satisfactory for all kinds of freight service; particularly on account of the low first cost and the guarantee by the manufacturers of a definite life or mileage, in addition to an allowance for scrap value when worn to the limit of safety. The wheel makers also are willing to furnish a cast iron wheel guaranteed for use under cars of 70 tons capacity; but as yet there are only a few of the latter, for special service such as the transportation of bridge members, large castings or heavy guns.

A very timely discussion was held on the inspection of box cars, with particular reference to the transportation of their contents without loss or damage. At all important divisional points, freight cars are inspected in the running gear, couplers and air brakes, in order to determine whether the cars are fit to run. An examination of the roofs and doors for leaks; of the floors to determine whether there is any oil, lime, acid or any other wet or corrosive substance that would damage certain classes of goods; or of the sides and ends for the removal of projecting nails, splintered boards, etc., is seldom thoroughly done. Then again, many cars are sent out loaded but so insecurely fastened that the theft of their contents is an easy matter and one that is constantly occurring. The members agreed that much more detailed inspection of cars is needed, as is evidenced by the enormous sums of money constantly paid out by railroad companies in settlement of claims for loss and damage of goods

in transit. They also urged upon all their fellow members the serious consideration of stouter construction, better materials and more frequent inspection of all parts of box cars in order to reduce the loss from the causes mentioned.

Owing to the increasing variety of the distillates of petroleum that must be accepted for shipment in bulk, the M. C. B. Association has found it necessary to promulgate specifications for the construction of tank cars for the transportation of different kinds of oils, naphthas, benzine, etc., to cover not only the material to be used in the tank plates, but also the method of construction, whether riveting or welding, and the size and location of the safety valves on the same. These specifications are also in accordance with the requirements of the Inter-State Commerce Commission on the same subject. Safety valves on tank cars must be set so as to blow off at a specified pressure, in proportion to the vapor tension of the liquids contained; and must operate and relieve the pressure when the vapor pressure increases by reason of the heat developed by any fire to which the car may be exposed, either by reason of wreck or a conflagration near the track.

A committee reported to the convention that the railroads have great difficulty in securing satisfactory rubber hose for air brake and signal connections. They find that some hose stretches too much, becomes soft, porous and leaky; and, on the other hand, some hose becomes brittle, and cracks, also causing air leakage. It is a matter of common knowledge among engineers and trainmen that locomotive air pumps in freight service are overworked; and this is largely because in a long train there are usually many leaky hose lengths to which air must be supplied in order to maintain normal pressure in the train pipe. The committee has drawn up specifications covering the quality of rubber and canvas to be used in the manufacture of standard air-brake hose.

Another question to which the convention gave considerable attention and discussion was the report on the electric lighting of trains. As is well known, there are three principal systems in use: (a) the "head end" system, employing an engine-driven generator in the baggage car; steam for the engine being supplied from the locomotive; (b) storage batteries carried in boxes under each car; and (c) the axle lighting system, having a generator mounted on one of the trucks of each car and driven by a belt passing over a pulley on the axle. This system also employs a storage battery as an auxiliary, to supply electricity when the train is not running as well as at speeds less than seventeen miles per hour. Two standard voltages, 30 and 60 volts, are in use; the tungsten lamp is now in common use for this kind of lighting, in fact, is used almost exclusively, and a great deal of study and experimentation has been turned upon finding the best kind and shape of shade to furnish pleasant illumination, bright enough for reading, without objectionable glare. Car wiring is put in regular conduit, and all circuits are brought to a switch panel in the car and provided with approved types of fuses. Few people realize the advance that has been made in the art of train lighting during the past two years; and in this connection the Association of Railway Electrical Engineers has done a great deal of work in developing the details of successful electric lighting for trains; not only in designing new apparatus, but in perfecting mechanical appliances for axle mountings, battery boxes, etc.

Other topics presented and discussed were those on car coupler side clearance and standard dimensions, best location of train pipe for steam heat connection, freight car springs and cast steel truck frames. The committee on brake shoe tests also reported progress in the investigation of rate of retardation of revolving car wheels by brake shoes at different pressures. It was stated, however, that the results on the brake shoe testing machine are not strictly comparable with service conditions, where the wheel is rolling along a rail, and, that consequently the conclusions must be accepted with caution.

The subject of car shop apprentices was brought up, and the consensus of opinion seemed to be that boys who enter a shop as apprentices do not have sufficient encouragement held out to them to induce them to continue in the car department of a railway after they have become first-class workmen. In consideration of the knowledge and skill acquired during apprenticeship, many young men seek employment where they can obtain better pay; usually with the railway equipment manufacturers; so that the railway companies have a rather limited number of trained, skilled men upon whom to depend for making promotions.

The sessions of the M. C. B. Association closed on June 14th, and were followed a few days later, June 18th, by those of the Master Mechanics' Convention, held also at Atlantic City.

Experiments with Blue Glass

(*Concluded from page 11.*)

Through two or more thicknesses of blue glass look at a lighted candle placed at a distance of more than six feet from your eye. While so doing hold your forefinger vertically in contact with one corner of your eye and bring it slowly toward the center of the eye until it intercepts a part and only a part of the beam of light which passes through your pupil (see the accompanying figure), that is, until the light of the candle suddenly becomes dimmer. Instead of one flame you will then perceive two. They stand side by side: one is blue, but the other is as red as blood, without any admixture of blue. Thanks to the anachromatism of the human eye, the crystalline lens acts in that case as a prism and the suppression, through the cobalt glass, of almost every intermediate color between the two extremes of the spectrum allows the clear separation of the red from the blue. As to the forefinger its object is to close the central part of the pupil and to allow the passing of light only through the most anachromatic part of the crystalline lens, i. e., its margin.

Chancing one day to look through two glasses, one blue and one yellow, placed one behind the other, the physicist Sinler was amazed to find out that while other objects were but little changed, foliage and grass had become of an intensely red color. A glance at the spectrum of the light reflected by chlorophyl explains the mystery. This spectrum contains an extraordinary amount of the extreme red for which the cobalt glass is transparent. Most other colors are stopped either by the blue or by the yellow glass. The experiment is well worth being made, as the appearance of a landscape with everything about as usual except that every leaf or bit of grass is as red as blood is extremely fantastic. Unless the blue glass is very thick and dark two pieces, one behind the other, must be used. One yellow glass is enough. It is essential that the vegetation be in full sunlight. Diffused light on a cloudy day gives no results at all.

Although the writer has come across more than one mention of the curious experiment he is about to describe, he has been unable to find the name of its author. Besides the blue glass a concentrated solution of quinine sulphate, to which a few drops of sulphuric acid have been added, is needed. With this liquid used as ink and a pen cut out of any piece of wood (a steel pen should not be used), the experimenter writes on a sheet of white paper. When dry, the script cannot be read, as quinine sulphate is as white as the paper. But if it is placed in a dark room, in such a position as to be lighted only, or almost only, by a beam of sunlight which has passed through a blue cobalt glass, the handwriting, while so lighted, is plainly visible in white on a blue field. No other sympathetic ink equals quinine sulphate in the rapidity with which the script can be made to appear or to disappear.

The writer has failed to obtain similar results with a blue screen made of a concentrated solution of copper sulphate, which absorbs the red and most of the

violet and ultra-violet rays. Methylene blue, which allows the passing of these rays, gave positive results. It is probable that the explanation of the phenomenon lies in the absorption by the cobalt glass of such rays as do not cause the fluorescence of quinine sulphate. The paper is thus considerably darkened, but the fluorescent script remains about as luminous as if in white light.

Superheated Steam in Locomotive Service

AN Abstract of Publication No. 127 of the Carnegie Institution of Washington, by W. F. M. Goss, has just been issued as Bulletin No. 57 of the Engineering Experiment Station of the University of Illinois.

This bulletin gives a summary of foreign practice in the use of superheated steam; it contains a report of an elaborate series of tests made upon an American locomotive to determine the precise advantage to be derived from superheating under various conditions of locomotive service; and it shows that the use of superheated steam is not attended by serious difficulties. The superheater is easily maintained, and its presence as a detail of locomotive mechanism introduces no new problems in maintenance. The superheater improves the efficiency of the locomotive through the saving of coal and water. Tests run with boiler pressures varying from 120 to 240 pounds per square inch, for which the steam was superheated approximately 150 deg. Fahr., prove that neither the steam nor the coal consumption is materially affected by considerable changes in boiler pressure. This fact justifies the use of comparatively low pressures in connection with superheating. The saving in water consumption was found to vary from 18 per cent at a boiler pressure of 120 pounds to 9 per cent at a boiler pressure of 240 pounds, the corresponding saving in coal varying from 17 per cent to 6 per cent between pressures of 120 pounds and 240 pounds. The power capacity of the superheating locomotive was found to be greater than that of a saturated steam locomotive of the same general dimensions.

Copies of Bulletin No. 57 may be obtained upon application to W. F. M. Goss, Director of the Engineering Experiment Station, University of Illinois, Urbana, Illinois.

The Current Supplement

THE current issue, No. 1905, of our SUPPLEMENT brings a number of interesting and important articles. Mr. Cooley reports on some tests of vacuum cleaners.—Mr. Miller gives a concrete example of the applications of Motion Study to the improvement of manufacturing efficiency.—Mr. John Jay Ide, who is well known to our readers, describes the Tatin-Paulhan Aero Torpedo.—Prof. E. F. Northrup gives a most interesting survey of the range of temperatures known to us in the laboratory and in nature, and of the properties of matter as it is exposed to different portions of this large range.—There is no nation in the world's history which has shown such rapid rise from comparative obscurity to modern civilization as the Japanese. Something of what the Japanese have done in science is told us in an article entitled "Some Japanese Scientists."—The utilization of water-power through the medium of electricity, for industrial purposes, is a subject that can never lose its interest. An article on this subject, illustrated by a front page and other engravings, forms part of the present issue.—Mr. Hartley M. Phelps tells us of American industrial enterprise in India.—Mr. Tweedy writes on the Cold Storage of Furs and Fabrics.—Prof. Houssay, of Paris, discusses the body shape of fishes as influenced by the effect of water pressure.—Those of our readers who own microscopes will be much interested in an article on the fine adjustment of these instruments.—The subject of baldness and grayness, treated of in a special article, is one which is apt, sooner or later, to engage the attention of all of us.

SIXTY-EIGHTH YEAR

SCIENTIFIC AMERICAN

THE WEEKLY JOURNAL OF PRACTICAL INFORMATION

VOLUME CVII.] NUMBER 2.] NEW YORK, JULY 13, 1912 [PRICE 15 CENTS $3.00 A YEAR

Prof. Elie Metchnikoff

The Most Distinguished of Living Bacteriologists and His Work

By Sir Ray Lankester, K.C.B. and F.R.S.

[THE following article is abstracted from an essay entitled "Metchnikoff and Tolstoy" by Sir Ray Lankester, forming one of a series of popular scientific discourses collected in book form under the title "Science From an Easy Chair" (Methuen and Co.). The author enjoys a personal acquaintance with Prof. Metchnikoff and, is therefore, able to give first hand information on a study of prolonging human life, which has recently attracted wide-spread attention.—EDITOR.]

The recognition of the derivation of man from animal ancestors, and of the complete community of the structure and the chemical activity of the organs of man with those of the organs of animals, has made the study of the diseases of animals a necessary feature in the understanding of the diseases of man. The far-reaching principle of Darwin that the mechanisms and processes observed in the bodies of plants and of animals (including man) must have been selected in the struggle for existence and perpetuated, because of their utility, led Metchnikoff to inquire what is the value or use of the process called inflammation and of the "eating corpuscles" or "phagocytes" (so called by him) which wander from the blood into inflamed tissues. This question had led him to the discovery that the phagocytes engulf and destroy disease-germs, and are the great protectors of the animal and human body against bacteria and others germs which enter cut and wounded surfaces, and would start disease were there not "inflammation," which is nothing more nor less than a nerve-regulated stagnation of the circulation of the blood at the wounded spot, and the consequent arrival at this spot of thousands of "phagocytes," which pass out of the stagnant blood through the walls of the fine blood-vessels. These armies of phagocytes proceed to eat up and destroy all the germs which fall on to the wound—from the air, from dirty surfaces, and from the skin. The utility of inflammation and its gradual development, according to Darwinian principles, in the animal series, was shown over twenty years ago by Metchnikoff. His important work on "immunity" and on infection and on protection against germ-caused disease is thus seen to be one of the many flourishing and valuable branches of knowledge which have originated from Darwin's great conception and his example in experiment and inquiry.

Metchnikoff is now devoting all his attention to the possibility of prolonging human life. The facts seem to show that if we ate and drank only what is best for us, and led lives regulated by reason and knowledge, we should, nearly all, attain to eighty or even one hundred years of age, having healthy minds and healthy bodies. We should die quietly and comfortably at the end, with much the same feeling of contentment in well-earned repose as that which we now experience in going to sleep at the end of a long and happy day of healthy exercise and activity. Metchnikoff thinks that the cause of too early death may be ascertained, and when ascertained avoided or removed. In 1870, in a little book on "Comparative Longevity," I distinguished what we may call the "possible life" or "potential longevity," of any given human being from his or her "expectation" of life. Potential longevity has been well called our "lease" of life. It is probably not very different in different races of men or individuals, and is probably higher than King David thought, being one hundred to one hundred and twenty years, and not merely seventy years. We all, or nearly all, fail to last out our "lease" owing to accidents, violence, and avoidable, as well as unavoidable, disease; so that seventy years is named as our tenure when the injury done to us by unhealthy modes of life and by actual disease are considered as inevitable. Metchnikoff proposes to discover and to avoid those conditions which "wear down" most of us and produce "senility" and "death" before we have really run out our lease of life.

Human beings die most abundantly in the earliest years of life. Statistics show that at birth the chance or expectation of life is only forty-five years, while at ten years old you may expect to live to be sixty-one. At thirty you have not a much better chance—you will probably, if you are what is called a "healthy" life, die when you are sixty-five. But if you survive to be fifty, you may expect, if you have not any obvious disease or signs of "break up," another twenty years, and will probably die at seventy; surviving to sixty, you may expect, if you are what passes for "healthy," to live to seventy-three. Now, it is especially with regard to life after forty or fifty years of age that Metchnikoff is interested. Those who have survived the special dangers and difficulties of youth, and have arrived at this mature age, ought to be able to realize much more frequently than they do something like the full "lease of life." There seems to be no reason why they should not avoid the usual rapid "senile changes" or weakness of old age, and survive, as a few actually do, to something like one hundred. The causes of "senile change" and the way to defeat their operation are what Metchnikoff is studying. Hardening of the walls of the arteries set up by certain avoidable disease contracted in earlier life, and by the use of alcohol (not only to the degree which we call "drunkenness," but to such a degree as to make one depend on it as a "pick-me-up") is an undoubted cause of that weakness and liability to succumb to other diseases which is so general after fifty years of age. The causes which produce hardened arteries can be avoided.

Another cause of senile changes is declared by Metchnikoff to arise from the continual absorption of poisonous substances produced by the decomposition of partially digested food in the lower bowel or large intestine. This is at present the chief subject of his study. It is to prevent the formation of these poisons that he has introduced the use of sour milk, prepared with the lactic ferment.

Metchnikoff has made some very interesting experiments in progress with animals. He used the large tropical fruit-eating bats, or "flying foxes" and also monkeys. Bats have a very short intestine, and very few bacteria and of very few kinds are to be found in its contents. On the other hand, there are as many as thirty distinct kinds of bacteria producing putrefaction or other chemical change in the digestive canal of man—and their quantity is gigantic. They pervade the whole contents of the human digestive canal by millions. By properly feeding the flying foxes in his laboratory in Paris, Metchnikoff actually succeeded in getting rid of all bacteria from their digestive canal, so that he obtained adult mammalian animals, not very remote from man in their structure, food and internal chemistry, which are absolutely free from the intestinal parasitic bacteria which he supposes to cause poisoning and senile changes in man. It is obvious, without pursuing the matter into further detail here, that Metchnikoff is in a position to test his views as to the action of particular kinds of bacteria—he has animals which are free from them. He can make an experiment, keeping some of his bats still free from bacteria and causing some to be largely infected by this or that kind, and he can compare the result in regard to the health and chemical condition of the animals. So, too, the patients from whom the lower intestine has been removed, may very probably furnish him (through his assistant who remains in London) with important facts for comparison with the condition of persons who have not been deprived of this part of the digestive apparatus.

I have given this sketch of what my friend is doing, in order to furnish some notion of the kind of investigation which he pursues. He does not expect to extend the "lease" of human life, but by ascertaining in a definite scientific way the true rules of internal and external "hygiene" he does hope to give mankind an increased "expectation" of life, in fact, to enable a vastly larger number of men and women to enjoy that lease to the full, and to die without disappointment and regret, even with contentment and pleasure, at the end of it.

Metchnikoff was in Russia in the spring of 1909, and spent a day with Tolstoi. They were "feted" and photographed together, the greatest artist and the greatest scientist of Russia. Tolstoi is 81 years of age. He took Metchnikoff out alone for a drive in his pony-cart so as to talk with him without interruption. "What do you think of life?" was the first question he asked, and one which it took my friend some time to answer. In regard to vegetarianism the two great men did not agree. When Metchnikoff declared that there was less cruelty on man's part in killing wild animals to eat them than in leaving them to die by the tooth and claw of predaceous animals or from starvation, Tolstoi observed that that was argument and reason, and that he paid no attention to them; he only guided himself (he said) by sentiment, which he felt sure told him what was good and right!

SCIENTIFIC AMERICAN

Founded 1845

NEW YORK, SATURDAY, JULY 13, 1912

Published by Munn & Co., Incorporated. Charles Allen Munn, President
Frederick Converse Beach, Secretary and Treasurer,
all at 361 Broadway, New York

Entered at the Post Office of New York, N. Y., as Second Class Matter
Trade Mark Registered in the United States Patent Office

Subscription Rates

Subscription one year	$3.00
Postage prepaid in United States and possessions, Mexico, Cuba and Panama	
Subscriptions for Foreign Countries, one year, postage prepaid,	4.50
Subscriptions for Canada, one year, postage prepaid,	3.75

The Scientific American Publications

Scientific American (established 1845)	per year	$3.00
Scientific American Supplement (established 1876)		5.00
American Homes and Gardens		3.00

The combined subscription rates and rates to foreign countries including Canada, will be furnished upon application.
Remit by postal or express money order, bank draft or check.

Munn & Co., Inc., 361 Broadway, New York

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are *sharp*, the articles *short*, and the facts *authentic*, the contributions will receive special attention. Accepted articles will be paid for at regular space rates.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

No Contest for the Gould-Scientific American Prize

FOR the second time Mr. Edwin Gould's generous offer of $15,000 for a safe, multi-motor, flying machine has failed to meet with any effective response. The Contest Committee was present at the field of the Hempstead Plains Aviation Company, which had been kindly placed at their disposal for July 4th, and as none of the entrants had a machine on the grounds, the Committee had to go through the formality of declaring that there was no contest. Mr. Gould does not feel justified in making a further extension of time, and the prize is now definitely withdrawn.

Of the eleven entrants, only three or four seem to have made any serious effort to build a machine that would comply with the conditions. One of these, a biplane, built by the Burgess-Curtis Company for Howard Gill, was completed, tested in flight and ready to ship, and we greatly regret that the meritorious attempt of this young and promising aviator should have been frustrated by the failure of any other entrant to have his machine ready for the contest.

So far as the other entrants are concerned, the SCIENTIFIC AMERICAN is of the opinion that the failure of the few that made an effort to build machines was due, not to lack of interest in the competition, but rather to the want of adequate means and facilities. But what is to be said of the indifference of the various aeroplane construction companies outside of the Burgess-Curtis, who, having both the aeroplanes and the motors, and experienced pilots, might have placed machines on the field at a moderate cost and with little inconvenience?

We are driven to the conclusion that they are more concerned with gate receipts at flying meets than they are with the development of the art itself for its own sake—a deplorable condition to exist in that very country which gave birth to the first practicable aeroplane.

It cannot be objected that the conditions imposed for this contest were too onerous. Certainly they were not impossible, for while our aeroplane builders are holding back, Germany has shown us the way in most brilliant fashion. The flight of Hirth with a passenger from Vienna to Berlin in a two-motor, two-propeller monoplane, at a reputed average speed of sixty miles an hour, was a feat far more difficult, surely, than that demanded under the conditions of the Gould-SCIENTIFIC AMERICAN Prize.

Nor can it be urged that the object which prompted Mr. Gould's offer was wanting in appeal. If we were asked to name the quality in an aeroplane which, just now, is most urgent in its demand for consideration, we should unhesitatingly name that of safety. The alarming number of aviators of experience who have fallen to sudden death during the past few weeks should be taken as a loud call for any device of a practicable nature that will render aviation reasonably safe—and among these, the provision of separate motors and propellers, with one plant normally in reserve, must always hold a high place. The prize which is now withdrawn was notable as the first and only offer made for an improvement whose object was to protect the life of the aviator, and render the new art reasonably safe.

Mr. Gould's generosity, to say nothing of the several inducements offered by certain leading papers, has silenced the complaint of the aviators that they do not receive, in this country, the financial assistance which has carried aviation in Europe to its present commanding position.

The Death of Melvin Vaniman

WE have spoken somewhat glibly of the "Conquest of the Air," until the phrase has become trite, and savors of platitude. Yet almost daily we are reminded only too forcibly that the air is not yet conquered, that the battle with the element is still being waged, and is claiming its full toll of human life. We follow with interest and pride the records that are newly established almost every week in the field of aeronautics. A mournful record belongs to last week. On Tuesday, July 2nd, Melvin Vaniman, with his crew of four men, met their death as the result of an explosion aboard the "Akron," the airship on which Vaniman hoped to cross the Atlantic; on the previous day Miss Quimby and Mr. Willard were dashed to death from a monoplane.

When we read the roll of victims that the air has claimed, or the account of the heroic manner in which the men aboard the "Titanic" met their death, for a moment some of us may feel our scientific creed shaken. What of the principle of the survival of the fittest? Is it not the brave and daring, the heroes, that are being swept away, while their less enterprising or more timid fellows are preserved in the safety of common everyday life? Are the brave, therefore, to be classed among the "unfit," to be weeded out in the progress of time? The answer is not far to seek. Some individuals must be sacrificed that the community may benefit. Just how this benefit arises we may not always be able to see in any one specific instance. But can we doubt that the nation which harbors such characters as Vaniman, or whose men stand up under the test of death as did the passengers of the "Titanic," will carry off the victory in the battle of nations, whether in actual warfare or in the industrial contest of peace? Such a nation is "fit," because it numbers in its population men who risk their life in the cause of the advancement of arts and knowledge, or who sacrifice it unflinchingly for the sake of high principles.

Vaniman, like many an inventor before him, died a victim to his own theories; and his sudden taking off is rendered the more pitiful by the fact that his theory was correct, and had he only waited for the completion of his new "wire-cloth" machine, he might have escaped disaster.

In seeking to construct a dirigible of constant displacement, with a shell of sufficient strength to withstand the increase of pressure due to rise of temperature, he was treading the one road—at least so we judge—along which development of the dirigible must proceed, if it is to become a really practical machine.

Let no one make the mistake of placing this man among the mere dreamers. He was practical, clear-sighted, and logical. His conception of a constant-displacement machine was based upon sound theory and practical experience, gained in his earlier work. His comparison, in conversation with the writer, of the spherical drifting balloon, with its steady loss of gas, to a ship that is launched with the certainty that it is leaking so badly that it will soon go to the bottom, was quite to the point. "A ship is water-tight and rigid, and my airship must be reasonably rigid and gastight," he said.

Vaniman has left behind him in his wire-cloth fabric a material which may yet prove to be the solution of a hitherto unsolved problem. The failure of his weaker rubber-cloth fabric to stand the tangential stress proves only that in this particular case it was unequal to its duty. The wire-cloth is over 30 times stronger, and it is to be hoped that the line of investigation which has been opened by Vaniman will be followed up by the interests which were behind his meritorious if tragic attempt.

Doctors of Civilization

READ the terse yet masterful account that Thucydides gives of the "Black Death," a scourge which, despite their remarkable civilization, the ancient peoples clustered in Southeastern Europe and Asia Minor were unable to combat, or peruse Pepys' description of the terrible ravages of the Great Plague in London, and the thought strikes home that the gregarious instinct of man cannot be satisfied without paying a tragic toll. The diseases of perilous occupations, the accidents due to unprotected machinery, the ills obviously caused by poor ventilation, all these can be avoided by the ingenuity of the architect and the engineer. But the pests that have decimated even a rural population are not prevented in any obvious way. Their origin is hidden in wells that apparently yield only pure water, in the bites of insects apparently harmless. They are, in truth, diseases of civilization, which require for their eradication scientific investigation as painstaking and self-sacrificing as the researches that have given us the wonderful antitoxins and sera by which we cure typhoid fever, diphtheria, pneumonia and other maladies, [illegible].

Not until the bacteriologist with his microscope and his stains had discovered the germs, invisible to the naked eye, that are responsible for most of the ills which flesh is heir to, did it become possible to create the modern profession of sanitary engineering—to educate, in a word, the doctor of civilization. Prevention is the watchword of that new profession—prevention of the conditions under which deadly bacteria may thrive and prevention of the transmission of these bacteria should they breed. Not without the sacrifice of men who could ill be spared has this truth been learned. Heroes have been found, willing to subject themselves to the stings of bacteria-carrying insects, in order to prove that not the exhalations of swamps but the natural inoculating needle of the mosquito is the real cause of some infectious diseases; that *miasmas* do not in themselves cause ills, but simply aid the breeding of the living vehicles that carry disease germs.

Within the lifetime of living men it was thought that only a physician was fitted to be head of a Board of Health. Even in the smaller towns a medical man is still found intrusted with the well-being of hundreds and perhaps thousands of town dwellers. Gradually, the new doctor of civilization, the sanitary engineer, the public health expert trained to cope not with the ills of individual human beings but with epidemics that devastate whole communities, is coming to the front. Such is the need for these men that our technical institutions are now offering courses in sanitary engineering. To the Massachusetts Institute of Technology belongs the credit of having, years ago, established the first of these under the guidance of Prof. W. T. Sedgwick. Other institutions soon followed. They have all justified their existence by graduating many students, now actively and successfully engaged in public health work. Not many years will pass when the health of every community will be intrusted not to a graduate physician but to a trained public health expert.

Lunacy and Morals

CHIEF SURGEON PICQUE, of the Seine Lunatic Asylum, is reported to have addressed the Academy of Medicine in Paris on the operative treatment of forms of insanity arising out of appreciable lesions, such as abscesses and tumors of the brain and nervous system; or out of such affections of other organs, remediable by operation, as may affect cerebration through extension of their toxic products in the lymph and blood channels. Unquestionably such surgery may prove effective; the like work of other surgeons has proved so. In some idiots, moreover, mental regeneration seemingly miraculous has come after thyroid transplantation, or after the medical administration of the thyroid extract of the sheep.

Here there is no occasion for skepticism. One does not, however, altogether follow those who claim surgery to be efficient in the cure of human immorality. A brain tumor is a tangible, material thing; but an immorality (or is it an un-morality?) is an entity so metaphysical, so conditioned upon the will, that it were difficult to see how surgery can be effective in the premises. And yet it is worthy of reflection that in any prison one sees microcephalics, scaphocephalics and other unfortunates so born with anatomical stigmata that their moral sense is blunted or perverted. Such are unable to feel responsible for whatever unlawful acts they have committed; the insane asylum, not the prison, should be their place of confinement.

The difficulty is that one cannot always see clearly the line separating responsible wickedness from acts against the public peace which have their origin in perversities of the psychic apparatus. The difficulty would be largely cleared up if definitions of mind and morality acceptable to everybody could be formulated. To the scientist morality is the crystallization of natural law, a definition that might help to some very fair conclusions.

Many humanitarians now hold extreme views as to irresponsibility for criminal acts—views which, if generally accepted, would surely imperil the social structure. It has indeed become very difficult, to such extreme has the pendulum now swung, to convict those who have committed the most heinous crimes. Besides, there is a tendency to make prisons so comfortable that one is puzzled why those against whom indictments have finally been secured, do not immediately enter these luxurious institutions, instead of wasting so much of the time of jurymen, and so much of the public funds, in proceedings which so rarely end in conviction. There is, moreover, constant agitation for the substitution of trepanning for hanging, of optometry for trial by jury; such depravity as may not be eradicated by the dentist, or by the nose and throat specialist, or by the adjustment of proper spectacles, may nevertheless, by the exercise of a little considerate patience, yield to deep breathing, or the rest cure, or the hot air apparatus, and the like.

Engineering

Gas Engines in High Altitudes.—A gas engine, says *Science Conspectus*, was erected several thousand feet above sea level. The engine did not give the power expected, and it was concluded that the loss was due to the altitude of the station. Upon investigation of the theoretical and practical considerations involved, it was found that there is a loss of about 1 per cent of the indicated horse-power for each 1,000 feet of increase in elevation. The effect with a low ratio of compression is slightly less than with a high degree of compression.

The Power of an Air Brake.—Some idea of the power of an air brake may be gained from the following facts: It takes a powerful locomotive drawing a train of ten passenger cars a distance of about five miles to reach a speed of sixty miles per hour on a straight and level track. The brakes will stop the same train from a speed of sixty miles per hour in 700 feet. Roughly, it may be stated, says *Science Conspectus*, that a train may be stopped by the brakes in about 3 per cent of the distance that must be covered to give it its speed.

Anti-"Baggage-Smasher" Mats.—We have received from the Pennsylvania Railroad Company drawings of an interesting and, we are told, very successful cushion for unloading baggage from trucks in baggage rooms. The mats, which are 22¼ inches wide by 4 feet 4 inches long, are made of four strips of hard wood, 4 inches wide by 4 feet 4 inches long, across which are nailed 24 pieces of scrap air-brake hose. We are informed that the mat does its work admirably, of which fact no doubt the prospective railroad traveler will take due notice and comfort.

Utilizing Panama Canal Plant.—We have received from Mr. Frank Vanmeter, of Canton, Ill., a suggestion that a part of the dredging and excavating plant at the Panama canal might be shipped, when the canal is completed, to the Mississippi Valley, and there used by the Government in re-building and enlarging the present levee system. It is suggested that the excess material dredged from the river might be utilized in filling up a part of the adjacent low-lying lands, and that this would at once serve the double purpose of increasing the flood capacity of the river and recovering land which is now subject to flooding.

Electrifying a Canadian Steam Railroad.—An important work of electrification is being done on a section of the Rossland Division of the Canadian Pacific Railway, in British Columbia, extending from Rossland to Castlegar Junction. The Rossland Division is 29.3 miles in length, and if the sidings and tracks in the yard are included, the total length of track to be electrified is 43 miles. Current at 60,000 volts will be received from the West Kootenay Power and Light Company, and the hauling will be done by four 75-ton electric locomotives. It is yet to be determined whether alternating current at 6,600 volts, or direct current at 2,400 volts, will be employed.

The World's Largest Building.—The first day of July the topmost piece of steel work was riveted in place on the Woolworth Building in New York. This structure is notable as being the loftiest building devoted to business purposes in the world. From the sidewalk to the top of the cupola is 750 feet, which is 50 feet more than the height of the Metropolitan Building in this city, and 138 feet more than the height of the Singer Building tower, also in New York. The building contains fifty-five stories in the tower. It is of the standard steel column and floor beam construction; but in order to take care of the enormous dead load and the great wind load, the columns are necessarily of unprecedented size.

The Inner Structure of Metal.—J. Alfred Ewing, in delivering the May lecture of the Institute of Metals, drew attention to the fact that when it was desired to examine a metal microscopically, the first step taken was to polish the section. As Dr. Beilby had shown in the previous May lecture, this polishing seriously affected the constitution of the surface, making it quite different from that of the metal below. It produced an amorphous layer, distinct in constitution from the crystalline structure, which became apparent when this layer was removed. This removal was commonly effected by a light chemical attack, the metal being etched by a weak acid. It could also be done by heating the specimen and subliming away or evaporating off the amorphous phase.

Cape Cod Canal Progress.—When the delegates of the recent International Navigation Congress visited Cape Cod, they were assured that this work would be opened to traffic during the winter of 1913, or at the latest in the spring of 1914. The canal will provide a 25-foot depth from Barnstable Bay to the 30-foot depth in Buzzards Bay, a distance of 12½ miles. The minimum width on the bottom will be 200 feet. The canal will enable ships to avoid the dangers of the stormy outside passage around Cape Cod, and it will shorten the distance from Boston for ships passing through Long Island Sound by 66 miles. Fifty thousand vessels of a total tonnage of 25,000,000 and carrying 500,000 passengers pass around Cape Cod every year, and the majority of this traffic, it is expected, will seek the shorter and more sheltered route.

Electricity

Condensers on Lighting Circuits.—*The use of condensers* to obtain better economy and power factor on the circuits of low-voltage lamps has been rendered possible by improvements in the manufacture of tinfoil and paraffined paper condensers. By immersing the condenser roll in melted paraffine after vacuum impregnation, and subjecting the paraffine to high mechanical pressure during cooling, thorough durability, and efficiencies up to 99 per cent at full load, are readily obtained.

Street Cleaning by Electricity.—In several German cities street washing machines driven and operated by storage batteries are in operation. The machine employed is a 3½-ton vehicle equipped with a 40-cell battery giving 200 ampere-hours at the 5-hour discharge rate, with traveling speeds of 4, 6 and 9 miles per hour. It carries a heavy tank of water, brushes, and rotating rubber scrapers. There are 24 of these machines at work in Berlin at present, with six special charging stations, and each machine covers 18 to 25 miles per day and costs less to operate than a horse-drawn machine.

A New Light-weight Storage Battery.—The present capacity of lead-plate storage batteries capable of withstanding the shocks of ordinary mechanical usage to which they are subjected in automobiles, electric cars, and railroad trains is stated to be 30 to 35 watt-hours per kilogramme of battery. The principal of the Royal Technical College, Copenhagen, has announced the invention of a lead-alloy storage battery the plates of which are extremely porous so as to increase the active surface in contact with the electrolyte. At a discharge current density of about 0.005 amperes per square centimeter, which is the normal for ordinary train-lighting cells, and an ampere-hour efficiency of 91 per cent, the capacity of the plate of the new battery is stated to be 4½ times that of the ordinary battery plate.

Crystallization of Metal Lamp Filaments.—It is well known that the metal filaments of modern incandescent lamps become more fragile after use. A recent investigation of the changes set up in metallic filaments by use, including a microphotographic study of both "drawn-wire" and "extruded" filaments, has proved that the continued high temperature at which the filaments are run causes the metal to crystallize. The coarse crystals which ultimately mean breakage of the filament are built up by accretion upon the fine crystals in the original structure of the metal. Drawn-wire filaments, having a finer initial crystallization, are stronger at first, but show no advantage over the extruded filaments after both have become crystallized.

Electric Lighting for the British House of Commons.—The electric lighting which it is proposed to substitute for gas in the debating chamber of the House of Commons is to consist of groups of three metal filament lamps inclosed in a holophane globe and placed over a square pane of amber tinted glass. This provides three thicknesses of glass, which are depended upon to cut off ultra-violet rays. Uniformity of illumination is to be secured by the dispersing effect of the globes. The amount of illumination on the benches, now obtained by gas lighting, is four-fifths of a candle-foot, and the same amount or more can be obtained by the electric light—one candle-foot being usually considered requisite for reading purposes.

Detecting the Proximity of Icebergs.—A Canadian physicist has devised a microthermometer for detecting the proximity of ice at sea by observing the temperature effects in the water currents around the mass of melting ice. The instrument for this purpose is inclosed in an iron cylinder, arranged to be submerged about five feet below the surface of the water and is connected by cable to an electrical registering and recording device on deck. This sensitive apparatus registers temperature variations otherwise entirely overlooked, and indicates the presence of an iceberg at a distance of half a mile. The character of the temperature changes and the rate at which the changes take place are found to be more significant for determining the presence of ice than the temperatures themselves.

Advantages of Electric Locomotives.—A recent paper on electric locomotives for the handling of freight in railroad yards and in mining brought out clearly certain advantages over steam locomotives apart from the elimination of fire and smoke and the difference in fuel efficiency of the central station boiler and engine and the (smaller) locomotive boiler and engine. The electric locomotive can be relied upon, as long as the line voltage is maintained, to develop its full power at any time, being independent of the state of a boiler, the skill of a fireman, or the quality of fuel. The track adhesion is better—sometimes as much as 20 per cent better—because the torque of the driving wheels is uniform throughout each revolution, and there is not the same tendency to slip when starting under load as in the steam locomotive. The traction can be increased indefinitely by sanding the rails, since the electric locomotive can draw power indefinitely from the line. No time is lost on the road for coaling, watering, boiler tending, or waiting for steam pressure to rise.

Science

Dr. de Quervain's Trans-Greenland Expedition is now under way, the party having sailed from Copenhagen for the west coast of Greenland the end of April.

Tenth International Geographic *Congress.*—*This* much-postponed meeting is, *according to the latest* announcement, to be *held in Rome in the week beginning March 27th, 1913.*

A Dry Month in England.—During April, 1912, the total rainfall registered at Greenwich observatory was only 0.02 inch. This is the driest month recorded at that observatory, at any period of the year, for 100 years.

Dr. S. Rona, late vice-director of the Meteorological and Magnetic Institute of Hungary (the national weather service of the country), has been appointed director of that institution.

Explorations in Iceland.—A remarkable series of explorations was carried out in Iceland during the years 1910 and 1911 by a Swiss traveler, Herm. Stoll, who covered a distance of over 5,000 kilometers (upward of 3,100 miles) in the course of the two years.

Finger Prints in Banks.—German banks, according to newspaper dispatches, have begun to introduce the finger print as a mark of identification on checks. The method is already in use in the United States.

Climatic Statistics of the British Isles.—A joint committee comprising two representatives of the Meteorological Office and two of the Royal Meteorological Society is planning the publication by these two organizations of a collection of climatic normals for the British Isles. Barometric pressure and wind direction will be first dealt with.

Designs for the Australian Capital.—According to press despatches the first prize in the competition for designs for the new seat of government of Australia, viz., £1,750 ($8,516), has been awarded to Walter Burley Griffin of Chicago, the second to Eliel Saarinen of Helsingfors, Finland, and the third to Alfred Agache of Paris. As decided three years ago, after long discussion, the new capital city is to be built in the Yass-Canberra district of New South Wales.

Another Attempt to Scale Mt. McKinley.—The Bulletin of the American Geographical Society reports that the expedition to Mt. McKinley which left Fairbanks, Alaska, on February 5th, fitted out by a newspaper of that town to attempt the ascent of the mountain, returned unsuccessful on April 10th. An elevation of 10,000 feet was reached on the north side of the mountain east of Peter Glacier, where precipitous ice cliffs prevented further progress.

The Harbor of Colombo.—In 1875 the late King Edward VII, then Prince of Wales, laid the first block of the southwest breakwater of the harbor of Colombo, Ceylon. Prior to that time the harbor had been an open roadstead, exposed to the full violence of the monsoons. On May 1st of the present year the Governor of Ceylon, Sir Henry McCallum, laid the final stone in an extension of the southwest breakwater, thus completing the construction of one of the finest artificial harbors in the world, which is a square mile in area and capable of accommodating 40 to 50 vessels of over 12,000 tons. The total cost of construction has amounted to about $15,000,000.

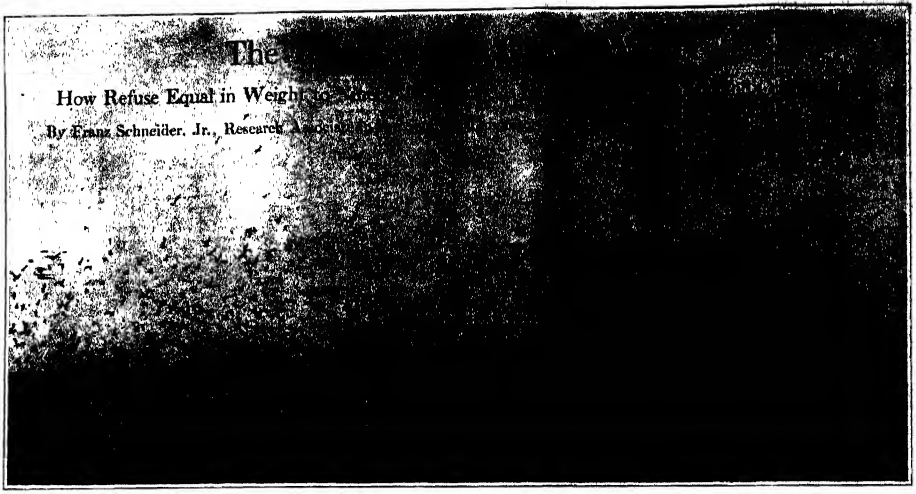
Banana Flour.—Banana flour specially prepared as a tonic food is making its appearance in Paris under the name of Bananéine. It is to be remarked that within a recent period this fruit was but little used in France, and even now its consumption is limited. However, measures are being taken to increase the importation, and it is said that 70 vessels were recently fitted up for bringing the fruit to Europe. Banana flour has a much more extended use in England than on the continent, but efforts are now made to introduce it in France owing to its great nutritious value. The bananéine is a preparation made for convenient use, and it contains 60 per cent of banana flour, this being put through a sterilizing process at the proper heat.

A Rubber Substitute from Sea Fish.—A press statement forwarded by Consul Frank W. Mahin of Amsterdam, tells of a factory established at Ymuiden at the mouth of the North Sea Canal in Holland to produce a substitute for rubber, and it is reported that the company operating the factory has succeeded in producing a substance having the qualities of rubber and some special advantages over the genuine. While the process is a secret the principal ingredient is said to be fresh sea fish, which are brought to Ymuiden in vast quantities by the Dutch fishing fleets. According to report 15 to 16 per cent of natural rubber is added to the fish, and the result is a substance as flexible and elastic as rubber, but much cheaper—about as 1.25 to 8 in price, compared with real rubber. The low price of this product will be caused partly by the by-products which are possible, for it is said that much albumen will be made from the fish and that half of the factory is arranged for the manufacture of fertilizer.

The

How Refuse Equal in Weigh

By Franz Schneider, Jr., Research A



Gulls in the wake of garbage scows.

AT the head of this article is a picture of the garbage disposal by dumping at sea, not a sanitary way, but at the same time in use by some of the large American cities. The number of gulls may serve as a measure of the enormous quantity of refuse, portions of which are almost certain to be stranded on neighboring beaches.

If the entire year's refuse of New York city could be gathered together, the resulting mass would equal in volume a cube about one eighth of a mile on an edge. This surprising volume is over three times that of the great pyramid of Ghizeh, and would accommodate one hundred and forty Washington monuments with ease. Looked at from another standpoint, the weight of this refuse would equal that of ninety such ships as the "Titanic" When it is remembered that this volume does not include sewage or other liquids, but only the dry, or relatively dry, parts of the city's wastes, it is evident that the problem of refuse disposal is one of the first magnitude, calling for great engineering skill and the expenditure of large sums of money

The material is burdensome not only on account of its great bulk, but because of its extremely heterogeneous nature In agricultural districts the matter is relatively simple: garbage is fed to the stock, old paper and other combustible material are quickly burned, and the unburnable rubbish goes to an unobjectionable dump heap. In the city, however, matters are much more complex. Ashes here become an important factor in the disposal problem, forming one half of the entire refuse by volume and two thirds by weight. Street sweepings, containing much horse manure and ordinary dirt in various guises, must also be cared for The diversified nature of the city's industries and occupations is, of course, what operates to make the refuse so extremely heterogeneous. Almost any conceivable object, ranging from orange peel to bicycles, and from mattresses to dead animals, may appear In attacking the problem, however, four general classes of refuse are recognized: garbage, ashes, rubbish, and street sweepings Special wastes—as from slaughter houses—will be encountered, but the main phases of the problem are indicated under the above headings Disposal may be said to have a two-fold object: to dispose of the material without nuisance or injury to health, and to attain this end at the minimum expense.

Methods of Collecting Garbage.

Any comprehensive plan for complete disposal must take cognizance of the methods of collection. If separate treatment is to be given to garbage and rubbish, it will be advantageous to have the householder put the two in separate receptacles, and separate systems of carting will also be indicated. If, on the other hand, the garbage and refuse are to be treated together, as they are in England, there will be no advantage in separation by the householder or in any separate systems of collection. The means of collection and disposal at present in vogue are almost as varied as the character of the material itself. There are different methods for each of our classes of refuse, and from these a very large number of plans for complete disposal may be devised. The determination of the best combination of methods for a given community is a matter of very considerable difficulty, and calls for special knowledge and engineering skill. It is sufficient here merely to note the inter-relations of disposal and collection schemes, and to pass on to a consideration of the principal methods in vogue in treating each of our four sub-divisions of refuse.

Let us consider first the disposal of garbage. In small communities the garbage is often sold or given to the farmers, an arrangement satisfactory in many cases from the standpoints of sanitation and cost. Again, it may be plowed into the ground, although this is now rarely practised. In larger communities collection and disposal to farmers is increasingly difficult, and this method becomes impracticable. Recourse is sometimes had in this case to mere dumping, either on land or water. The practice of dumping garbage on land is one that cannot be defended from aesthetic or sanitary standpoints. The dumps become ill-smelling eyesores, and are ideal places for breeding of flies. Dumping in water may be attended by serious nuisance arising from material drifting back onto the shores, and, like land dumping, is at best a profitless enterprise. When the community is of sufficient size, say someting like a hundred thousand population, these primitive methods may be discarded and more scientific ones—attaining more perfect disposal, and sometimes capable of actual profit—may be adopted. These are methods of reduction and incineration.

Reduction and Incineration.

In the so-called reduction treatment of garbage, the aim is to recover the grease from the material. Ordinary garbage contains, as a rule, 2 per cent, and sometimes as much as 3 per cent, by weight of grease. Reduction and the coincident recovery of grease are accomplished in two general ways. In the first, the garbage is cooked in large closed retorts by means of steam under pressure. After about a half hour's

Filling scows with refuse (not garbage) to be used in making new land.

Garbage, ashes, sweepings, when collected in the Borough of Richmond (New York) are thrown into a refuse destructor, where it is burnt into clinker. This clinker can be utilized in the same manner as broken stone in concrete construction.

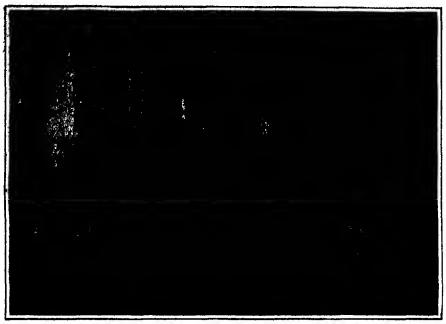
The tanks contain grease obtained from New York garbage.

digestion, the material is put through presses, removing the water and grease and leaving behind a comparatively dry cake, known as tankage, which has some value as fertilizer stock. The grease is skimmed from the water, purified roughly, and barreled for the market. In the other method of reduction the grease is extracted by some volatile solvent like naphtha. The garbage is sometimes dried as a preliminary to extraction. At all events, it is heated in contact with the solvent in closed vessels, after which the solvent is distilled off and the grease recovered. In both of these reduction processes the end products are the same, i. e., grease and fertilizer stock. Whether under ordinary conditions of operation the value of these products is sufficient to cover expenses is a debated question. In some instances, as at Columbus, O., the sale of the products has seemed to meet expenses. In a majority of cases, however, the process is carried on by private companies which must be subsidized by the city. This method of disposal is attractive from an economic standpoint, recovering, as it does, something valuable from an apparently valueless material. It is only fair to say, however, that reduction is usually attended by objectionable odors, making imperative the location of these plants at some distance from the city, and so adding to the expense of haulage. This may be regarded as distinctly American, being little practised abroad, where another method, that of incineration, is the favored one.

Garbage disposal by incineration must be considered with regard to our other classes of refuse. In this method the heat for incineration must be obtained not only from the garbage itself, but from ashes and other combustible waste. It is here that the distinction between incineration and the little-used cremation enters. In the former, the heat is obtained from the refuse itself; in the latter the garbage is burned at the expense of some regular fuel, such as coal or oil. Incineration is carried on in specially constructed furnaces. Garbage is mixed with the other refuse in the proper proportions and special devices are employed to feed the material into the furnaces so as to secure the best results. This method of disposal is entirely satisfactory from the sanitary standpoint, and gives, under proper operation, a slag or "clinker" which is valuable in construction work, while the resultant heat may be transformed into steam or electrical power. In the earlier attempts at incineration, using natural draft, the furnace temperatures were too low; objectionable smoke, noxious odors, and an undesirably soft clinker resulted. With the introduction of forced draft, these difficulties have disappeared, and in Europe, and in England especially, the disposal of the city's refuse by this method is complete, unobjectionable, sanitary, and sometimes profitable. Boilers are installed in the incinerators which will furnish relatively large amounts of valuable power. This may in turn be utilized for the generation of electricity, or for pumping when the incinerator is located in conjunction with water or sewage disposal works. On account of the unobjectionable nature of a properly designed and operated incinerator, it may be located in the center of the city, thus reducing the expense of haulage. As has already been indicated, there is a vast difference of opinion as to the comparative merits of reduction and incineration. Reduction has been a favored method in this country, but, owing to the large extent to which this process is in the hands of private interests, the facts as to the actual costs of the enterprises have not been fully available. In England, incineration has reached its highest development, and there appears to be an increasing use of this method in our own country.

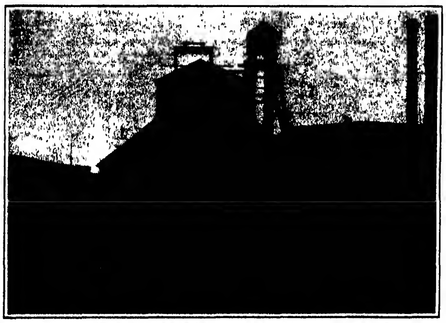
The Objectionable Method of Dumping.

The favorite way of disposing of ashes is by dumping, either on land or in the water. Ashes are often of real value as filling-in material for made land. Theoretically the land dump is merely unsightly and dusty; there is not the sanitary objection that may be urged against the garbage dump. But practically, from the fact that it is impossible to secure the proper separation of wastes by the tenant, the ash dumps in a crowded locality are largely garbage dumps with all their disadvantages. One must not forget, furthermore, that the ordinary run of ashes contains a very considerable amount of useful heating value which is lost when dumped.

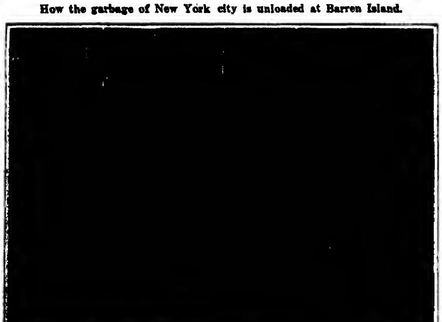


Chute and digesters at the Barren Island garbage reduction plant.

Filling in Riker's Island with New York city waste (ashes, dirt, etc.).



How the garbage of New York city is unloaded at Barren Island.



The presses of the Barren Island garbage reduction plant.

The dumping of ashes and rubbish into water is open to much the same objections as the similar dumping of garbage. Unless the material is carried far enough from shore, and conditions of wind and tide are favorable, serious nuisance is certain to arise. The cost of carrying the material an adequate distance from shore then may become very considerable.

Rubbish, making up about a quarter of the total by volume and a sixth by weight, may be sorted over, paper and other combustible material removed and sold or burned for heat, while there is some salvage in junk. This picking over of rubbish is very dusty work, and there is a question as to its effect upon the health of the workmen.

Street sweepings with their manure may be plowed into the ground, or may be dumped, or may be disposed of in the incinerator. The last of these alternatives is perhaps the most desirable.

These are, briefly, the various methods by which municipal refuse is now being disposed of. The more primitive methods, as the selling of garbage to farmers, and dumping indiscriminately, are showing a tendency to disappear. They are being replaced, more especially in the larger cities, by the more scientific methods of reduction and incineration. The actual detailed plan which will be the most efficient for a given community can be determined only after an investigation of the nature of its refuse, and by the character of the community itself and its surroundings. The objects which must be carried in mind in making a selection of methods are to remove the wastes quickly and completely from sight without the creation of nuisance or danger to health, the recovering of whatever is valuable, and the carrying on of the whole operation at the minimum expense. The field of refuse disposal is one in which there is great variety of opinion and, perhaps, a lack of scientific practice. It is one, however, which by its magnitude and financial importance is worthy of the attention of our best engineering talent.

Stains on Brick

THE brown, white and yellow stains which frequently disfigure brick buildings or walls are the result of a saline efflorescence which may sometimes be removed, according to the *Bibliothèque Universelle*, by washing with slightly acidulated water, when pure water proves inadequate. Prevention, however, is better than cure. The stains are caused by particles of soluble salts which have been carried to the surface by water and are then crystallized by evaporation. These comprise sulphates of potassium, sodium, aluminium, magnesium, and calcium, the last being the one commonest found and the one most resistant to rain. Chlorides and carbonates are also often found. These salts pre-exist either in the earth or in the waters used in manufacture, or in the mortar or sand, the latter being especially the case near the seashore, where sand from the beach is commonly used without the precaution of washing with fresh water. The entry of salts into the brick may occur during the baking, also, when the coal contains pyrites. Care should be taken to use water of low mineral content, especially as regards sulphates. Where only "sulphur water" is available it should be neutralized with a barium salt (the chloride or carbonate).

Wireless Telegraphy in Peru

WIRELESS communication has been established between Lima and Iquitos, across a vast stretch of the Andes, without the use of intermediate stations.

The Business Side of German Science—VII

Making Money With the Aid of Technically Trained Men

By Waldemar Kaempffert

[THIS is the seventh of a series of articles, written by the Managing Editor of the Scientific American, *on German industrial conditions. The author was sent abroad by the publishers for the express purpose of gathering the material on which the articles are based. In this and the article to follow, the part played by the technically trained man in German business is pictured.*

The amazing industrial development of modern Germany is to be attributed in large part to technical education and to the application of science to business. Capital and science work hand in hand. Every one of the great chemical discoveries of our times, most of them made in Germany, are the result not of haphazard experimenting, but of systematic research that has meant the expenditure of princely sums. All German manufacturing is so thoroughly saturated with science, that even the small producer practises on a miniature scale the methods of his larger rivals.]

THE notion that industrial success is largely a matter of luck dies hard. The huge American trust is a refutation of the oft-repeated fable that chance plays the largest part in business success. In Germany the evidence that conspicuous industrial success is not nowadays attained without well-directed effort, without the aid of technically trained men, is even more apparent than in America. Every prominent manufacturing firm in Germany maintains its department for industrial research.

The Wonderful System and Organization of the Germans.

The scientific work of a great German manufacturing company naturally divides itself into three classes. In one class men are to be found whose duty it is to control the manufacturing operations from a special laboratory; in another will be found men who are engaged to do research work pure and simple, for the purpose of improving existing manufacturing processes, devising new ones, or discovering new products; and finally in the third class are men who try out a new discovery on a miniature factory scale in order to determine its commercial possibilities.

Perhaps the finest example, outside of the chemical industry, of the technical control of manufacturing operations is to be found at the cast steel works of Krupp at Essen. The uniformity of the Essen products is to be attributed entirely to the rigorous scientific control of the entire cast steel plant. Each step in the manufacture of steel is checked up in the laboratory. Analyses are made by the hundred. The work has been so systematized that boys and young men do the actual work under the supervision of a chemist. Thus it becomes possible to make five hundred analyses of iron for carbon dioxide in a day. The laboratory workers simply see to it that Bunsen burners are lit, that retorts are boiling, and that filters are working properly. The supervising chemists are thus permitted to perform more important duties than that of watching a burette or a test tube. The laboratory workers are simply tools in the hands of their supervisors. They must be intelligent enough to perform the tasks assigned to them, but they must not be so intelligent that they are led to experiment for themselves. A similar method of employing intelligent workmen is followed by the United States Steel Corporation.

Research is not conducted simply by intelligent young men, but by university graduates, as may be supposed. The work is so subdivided that often two chemists working side by side may know nothing of the problem as a whole.

When after countless trials and failures a discovery is made by a research chemist that seems to have commercial possibilities, a small experimental plant is erected in which the same type of apparatus which is to be used for actual work operation, is employed. The conditions are industrial conditions. Little factories are equipped with little autoclaves, little filtering presses, little hydraulic presses, and little vats. At a great coal tar dye factory near Frankfurt I saw new dyes being tested on a small scale which involved practically the erecting of a miniature leather dyeing plant, a miniature paper dyeing plant, and a miniature textile dyeing plant. Thus the suitability of newly discovered dyes for special industries was ascertained. Upon the dozens of scientific men in the laboratories of a manufacturing company a strict masonic secrecy is imposed.

The Masonic Secrecy of the Laboratory.

It is even said that the director of one part of a great chemical works is not permitted to enter another part, and that the exact salary of an important man may not be known even to his own wife. So far is secrecy carried that a chemist in one laboratory is frequently totally ignorant of the work done in another laboratory in the same building. He is not allowed, with rare exceptions, to read papers before learned scientific societies, at least not without the consent of the firm. Buried away in the files of the great companies are probably the records of countless experiments which, if made public, would unquestionably advance the whole cause of science. The individual steps, already taken, must be painfully retraced by university professors who are working for no commercial object. At Essen, for example, I was told that the problem of gun erosion had been so far studied in the laboratory that the Krupps considered themselves ten years in advance of America on that point, but when I asked a chemist if he could refer me to any scientific publication in which the Krupp experiments are discussed, I was informed that they had not been published and probably would not be published; that they were, indeed, in the nature of trade secrets.

The Business Management of a German Manufacturing Company.

A German company is usually managed by a board, at least one member of which is a scientifically trained man, thoroughly conversant with the technical operations of the plant. One of the directors may be a lineal descendant of the original founder of the factory. He bears the name of his ancestors and continues the traditions of the old factory so long as they meet modern requirements. Another director is a glorified salesman. He is a man who has traveled much, who knows government officers, who may ultimately win the title of *Kommerzienrat* and who may even win a seat in the Reichstag. All of these men speak four or five languages and speak them well. With them on the board sit men who have represented the company in foreign countries and who travel six months in the year establishing agencies all over the world.

As a result of this partition of labor it is difficult for one man on the board to overawe the others. The purely business men know nothing of science; they must rely upon the technically informed member of the board. On the other hand, the technical director knows little of business and must accept the views on finance uttered by those members of the board who are better informed on such subjects than he. As a rule the directors are all men between thirty-five and fifty. Keen, alert, thoroughly informed of business conditions in foreign countries as well as their own, students of international politics, they are, in a word, broad-minded, cultured business men of the finest type. Even the chemists and engineers on the board of directors are essentially commercial men—commercial in the sense that they meet the mechanical requirements of the world. More, however, is required in that respect of the German than of the American engineer. The German enters into direct competition with French, German and Austrian technologists, who save at their command labor just as cheap as his and just as plentiful. We find him, therefore, thoroughly conversant with every phase of the industry in which he is employed. Nothing escapes him. He knows the source of raw material, its price both to him and to his foreign competitors, the manufacturing processes adopted in foreign countries and their efficiency as compared with his own. He studies the idiosyncrasies of the foreign market, and seeks to adapt himself to them. He knows the transportation facilities as well as any shipping agent. He makes a study of tariff schedules and customs laws of foreign countries.

These men usually have at their command a huge capital, represented by bonds and stocks valued at anywhere from five million to ten million dollars. The dye stuff industry of Germany as a whole represents an investment of about seven hundred and fifty million dollars. There are surpluses and reserve funds that amount in several cases to over two million dollars. Dividends of thirty-five per cent are occasionally allotted.

Because there is more science in German than in American industry there is less audacity. The offhand way in which many American business men will sink a hundred thousand dollars in an enterprise about which they know absolutely nothing, simply on the strength of a friend's well-meant advice, is without a counterpart in Germany. But when the board of directors of a German company has thoroughly studied a problem with the aid of competent men, when, as a result of that study, they have become thoroughly convinced that in the solution of the problem there lies a commercial possibility, money is spent freely in researches that may extend over years before it is possible to erect the first manufacturing plant. Thus the Badische Anilin und Soda Fabrik spent about four million dollars, it is said, to develop the present method of making synthetic indigo on an industrial scale. But the pecuniary sacrifices thus made were not risked for work that might or might not succeed. The result was foreseen and inevitable. The company knew that, given time, money and brains, the problem could be solved. Every path was explored, every chemical reaction that could possibly be employed was tried, with the result that every chemist now knows.

Millions for Research.

So, too, the Badische spent thousands and thousands of dollars in developing the Schoenherr process for the reduction of atmospheric nitrogen. The late Heinrich von Brunck, who did much to bring the company to its present eminence, realized how important was the solution of the problem. He placed ample funds at the disposal of Dr. Schoenherr. The Badische Company needed sodium nitrite for the production of anilin dyes. Previously, sodium nitrite had been made by the reduction of Chile nitrate with lead; but this method of production was costly. On every acre of the earth atmospheric nitrogen to the amount 31,000 tons presses; for eighty per cent of the air we breathe is composed of nitrogen. At that rate the air over every nine acres contains about two hundred and eighty thousand tons, equivalent to the amount of Chile saltpeter used in 1907. It is no easy matter to utilize the nitrogen of the atmosphere, simply because it is inert, in other words, because it refuses to combine very readily with other elements. Schoenherr devised an electrical method of fixing the nitrogen of the air, which is now familiar to the readers of this journal. As a result of the Schoenherr process, sodium nitrite is no longer reduced from Chile nitrate. Practically the entire supply of the world, valued at about one million dollars, is now obtained electrically.

So, too, the contact process of manufacturing sulphuric acid was developed by the Badische Company because of the demand of the indigo and alizarin manufacturer for a cheap concentrated sulphuric acid and sulphuric anhydrid. The demand for cheap sodium and chlorine induced the company to develop the electrolytic soda process. In a word, even the raw materials of a great industry are now made by cheap and efficient processes, scientifically developed.

The amount of work that must be done in systematically developing an industrial process along scientific lines is herculean. New methods must be worked out before a way is at last discovered of attacking the problem in hand. The work is slow because the investigator must follow an unbiased path. To spend two hundred thousand dollars a year and have nothing to show at the end of that period may seem sheer madness. Yet the German chemist knows that given time, money and brains, he must eventually succeed, knows that the commercial returns from a single great discovery are enormous. Of seventy-five research chemists whose collective salaries may vary from $75,000 to $200,000 a year, seventy may discover nothing, while the other five may discover products that mean a net return of a hundred thousand dollars a year for at least the life of an ordinary patent. That explains why some of the German chemical products notably drugs, seem inordinately high in price. Dr. Eberhardt of the Badische Company put the matter thus: "If capitalists are to employ inventors or to take up the exploiting of inventions as their business, as a means of earning their dividends, they must be recouped from successful inventions for the losses which they inevitably will incur from unsuccessful ones. Success can be made certain only by taking a large number of chances. A firm employs, let us say, one hundred chemists and engineers for the purpose of making and working out inventions. Some of these will never make an invention, but their salaries have to be paid. Few can be relied upon to deliver a paying invention every year, but the expense of their laboratories and their income has to be assured. If these conditions, essential for the establishment of chemical industry, were better realized, there would be less talk of the exorbitant prices charged by patentees for their products, and the ideas of many people as to fair terms for licenses—compulsory or otherwise—would have to be rearranged."

(To be concluded.)

Correspondence

A Defense of the Forest Service

To the Editor of the SCIENTIFIC AMERICAN:

My attention has just been called to the letter published in the SCIENTIFIC AMERICAN for June 1st under the heading "Comment on the Forest Bill." The bias of the writer is so obvious that I consider it unnecessary to make reply to most of his assertions; but certain passages in his letter compel attention.

Forest rangers are spoken of as "apparently imbued with the sole idea of 'riding' the sheep, cattle, and other industries therein, and principally the men who drive their stock across this country, or who have previously owned for years patented land around the water therein. In this way they make a part of their salary, while the rest comes out of the general Government."

This passage is so worded as to suggest that rangers are in the habit of levying on stockmen and others for their own personal benefit. What are the facts? The stockmen who graze their sheep and cattle on the National Forests pay the Government for the privilege, although they pay much less than it is worth and much less than they pay in the same regions for the same privilege on privately owned lands of equal grazing value. But all receipts from users of the forests are covered into the Treasury of the United States, while the salaries of all forest officers are paid entirely from the annual appropriations for the Forest Service made by Congress.

The writer also says:

"I think much money is now being unlawfully diverted and should be curbed, and wish you would interest yourselves in the matter further.

"If you want specific instances, I will furnish them."

I should certainly be glad to learn of any instances, specific or otherwise, of unlawful diversion of public funds.

It is one thing to criticise the national forest policy, concerning which there are bound to be honest differences of opinion and which, from the fact that it collides with the private interests of many individuals, is bound to be warmly debated; but it is quite another thing to indulge in reckless accusation of public officers. If I have allowed public funds to be mis-spent, I should be removed from my position. If forest rangers have been taking advantage of their position to practise extortion upon users of the national forests, they should be in jail. The writers of letters like the one which you published should, as a matter of public duty, lay their evidence before the officers who have power to institute criminal proceedings or to take the proper disciplinary action; or else they should retract their statements. There is no finer or more devoted body of public servants to be found anywhere than the men of the Forest Service, and in justice to them I cannot but protest vigorously against such imputations as your correspondent seems to wish to convey.

H. L. GRAVES, Forester.

United States Department of Agriculture, Forest Service, Washington, D. C.

[The letter of June 1st referred to by Mr. Graves was published without prejudice on our part, and we take much pleasure in presenting the above reply.—EDITOR.]

Maritime Canals and Restrictions on Size of Vessels

To the Editor of the SCIENTIFIC AMERICAN:

The SCIENTIFIC AMERICAN of even date is before me. On page 579 you have an item referring to Mr. Grunsky's report in reference to maritime canals and restrictions on the size of vessels. In order that your readers may be informed, I may say that Mr. Grunsky's recommendations were not approved. All the writers of the various reports, from several maritime nations, of which Mr. Grunsky was Reviewer, and who were present and some who were absent but were represented, unanimously protested against his "Conclusions," considering it to be the work of the International Navigation Congress to *promote* instead of to *restrict* navigation.

Mr. Grunsky presented five suggested "Conclusions," four of which were not accepted. The fifth was adopted as the sense of the Congress, which simply stated that a maritime canal should be five times as large as the immersed portion of the largest ship which is to use it, with a depth of one meter under the keel, these values being functions of the speed and somewhat of the volume of commerce, and are to be determined by local conditions.

ELMER L. CORTHELL, D.Sc.,
President Maritime Section of the Congress.

Bow Rudder for Ships

To the Editor of the SCIENTIFIC AMERICAN:

As many of the notable advances in various fields have been accomplished by a process entirely at variance with the customary and accepted way of doing things, I think my suggestion may not be as quixotic as it may seem at first glance. My idea is that a rudder should be at the bow of ocean steamships, in addition to the present one at the stern. If the "Titanic" had been so equipped, she would no doubt have been afloat to-day. The "Hawke" disaster would most surely have been averted. Let us follow the action of a rudder placed at the stern. If the bow is approaching an object, the action of a stern rudder is to swing the stern in the same direction as the object, and the bow is then pointed away, but before a rudder can point a boat away from any obstacle, the whole ship has been swung closer to it, which is the reason that it is difficult for a boat to swing directly away from alongside a wharf. Now let us follow the action of a rudder placed at the bow: On approaching an obstacle, the rudder would be turned away from the object, and would pull the bow of the boat directly away from it, and the ship would track after it, the same as an automobile does in turning a corner. In the case where the smaller boat was caught in the suction alongside a larger one, a bow rudder would have turned the bow away immediately, instead of which the stern rudder simply swung the stern of the boat in as well as the bow toward the larger boat. In the case of the "Titanic" a bow rudder would have drawn the bow aside immediately, instead of which the stern rudder in that case simply threw the ship partially broadside on the obstruction. Now this idea of placing a rudder at the bow will doubtless be criticised, and one of the first will be the objection to its exposed position. The rudder would not be damaged unless the ship runs into something bow on, a trick not appreciated by good seamen. Of course, the rudder would have to be hung somewhat differently from the stern, so that about three-fourths of it would follow the post, but I think it would be a simple matter to arrange the necessary details.

Toronto, Ont. A. C. LAWRENCE.

A New Phonograph

To the Editor of the SCIENTIFIC AMERICAN:

May I point out that the sound-recording apparatus of Mr. Lifschitz, described in your issue for April 27th, is not as novel as you seem to think it, as Mr. J. C. M. Stanton, Mr. R. C. Pierce, and myself constructed an exactly similar apparatus more than ten years ago. The greater portion of this apparatus still exists in my possession, as also one of the photographic records from which the reproducing strip was prepared, together with some of the latter.

As a delineator of the complicated curves which represent human speech, we found the photographic recording apparatus most efficient; but as a reproducer of sounds the system was not nearly so effective as the auxetophone of Sir Charles Parsons, which also operates by controlling the emission of air from a charged reservoir. Furthermore, the great length of ribbon that was required made the records unduly bulky.

London, England. A. A. CAMPBELL SWINTON.

The Fatal Aeroplane Accident at Boston

THE third Boston Aeroplane Meet, which was held from June 29th to July 7th, had a pall thrown over it at the close of the third day by the sudden death of its manager, Mr. W. A. P. Willard, and Miss Harriet Quimby, America's best-known aviatress.

The accident occurred at the close of a 20-minute flight to the Boston Light and back, which had been accomplished in a perfect manner by the skillful aviatress. She had risen, when at the farthest point, to a height of some 2,000 feet, and had been gradually descending all the way back. She had almost reached the field, and was at a height of about 1,000 feet, when the machine made a sudden dip and the body of her passenger, who had been seated in the rearmost of the two tandem seats, was thrown out of the machine and came hurtling to the earth. For a moment the pilot managed to right her machine, but the next instant it dived vertically and almost turned upside down, the result being that she too was thrown out, despite the strap which she had placed across the fuselage just in front of her waist.

As the two bodies fell with terrific speed and struck the water where it was only a yard deep, the aeroplane continued its plunge, but soon righted itself so that it descended at an angle of some 65 degrees and, striking in shallow water, turned upside down and remained on its back not severely damaged.

It is hard to find a plausible explanation of this terrible accident. Miss Quimby had flown her powerful 70 horse-power Blériot not more than half a dozen times, but she had never experienced any difficulty in managing it. On her first flight at Mineola, she used ballast in the shape of sand bags in the passenger's seat. She complained of the shifting of the sand, which she could feel when in flight, and afterward she never flew except with a passenger. Her machine was the latest military-type Blériot and she believed it perfectly safe as far as carrying a passenger was concerned, because the latter, being located some 4½ feet back of her own seat, could not interfere with her in any way—as had happened when the seats were side by side, with almost disastrous results.

As in the case of Moisant, who was flung from his machine as was Mr. Willard, the most plausible explanation of the accident seems to be gyroscopic force. A very slight difference in pressure against the front edge of the wing (which might be caused by a sudden turn of only a few degrees, occurring as a result of an "air hole" or of the pilot's foot slipping off the tiller) would, with the heavy 70 horse-power Gnome motor running at full speed, as it apparently was doing, develop a powerful and sudden force that would turn the machine instantly downward and whip the tail around through the arc of a circle so quickly that it might even break the fuselage. Eye witnesses agree that Willard was flung aloft and forward as from a sling, his body falling very close to the plunging machine, if, in fact, it did not hit the latter in its descent. This terrific gyroscopic force acts much more quickly and powerfully than does the force of gravity itself. Even a heavy, rapidly-revolving propeller on a non-rotary motor engenders sufficient gyroscopic force to put the aviator on his guard. In all probability many of the terrible accidents which have occurred with revolving-cylinder motors have been due to this unrecognized force, which takes the aviators unawares.

After Willard was pitched out, it appears to have been impossible for Miss Quimby to maintain the equilibrium of the monoplane sufficiently to make a safe descent. That she tried her best to do this, and that she succeeded for a moment, is seen in the fact that the aeroplane straightened out after its first dip and before its final plunge. It is also possible that the control post became jammed, owing to Miss Quimby reaching forward for something, or that it was thrown suddenly forward sufficiently to make the initial dive in this manner. It was in this way that Moisant made a sudden plunge to earth at Belmont Park one time when he was reaching forward to turn on the oil. There is also the possibility that a control wire may have broken, but as these were in duplicate this is very doubtful.

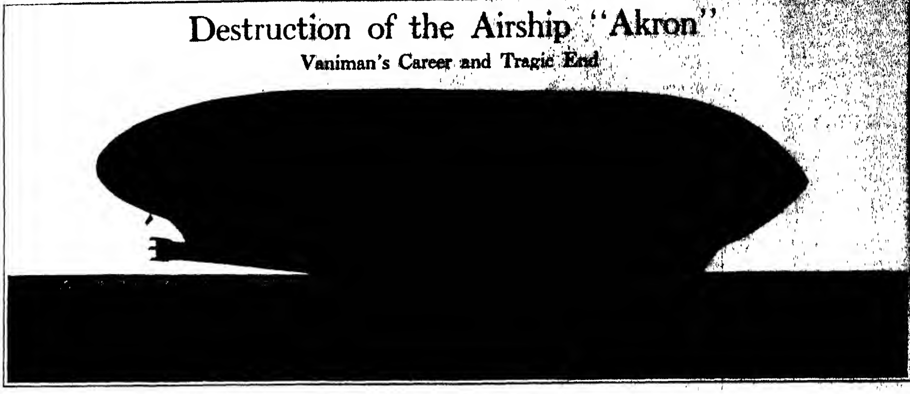
It is possible that a so-called hole in the air may have caused Miss Quimby's accident. The writer has a vivid recollection of seeing Earle Ovington suddenly tip to one side at an angle of 45 degrees when he experienced such a downward current over the edge of Long Island Sound at Bridgeport, Conn., over a year ago. Ovington saved the situation by diving, but he said when he alighted that had he not acted with the greatest celerity, and had he not been strapped in securely, he would have fallen to his death. The aeroplane in this instance tipped with great suddenness, one wing of the machine evidently passing into a swiftly descending current. In Miss Quimby's case, from the accounts of eye witnesses, it seems to have been a forward dive that pitched out the occupants of her machine.

Might it not be possible that this sudden dive was caused by the aeroplane striking a fast downward current head-on, even though it were going 70 to 80 miles an hour? At all events, such currents of air seem to be most numerous above the coast line, and aviators should be very careful when passing over it.

Miss Quimby, as the readers of the SCIENTIFIC AMERICAN are aware, had been flying for something less than a year. She learned to fly at the Moisant school at Mineola, under the tutelage of André Houpert; and only a day or two before she left for Boston, her former instructor had endeavored to persuade her to give up flying, as her sister aviatress, Miss Matilde Moisant, has done. She believed in the safety of the aeroplane if flown with discretion (and she never flew it otherwise), and it is certain that the accident which caused her death was not due to fancy flying or faulty manipulation of the machine by her in any way. Miss Quimby was the first woman to fly across the English Channel, a feat which she performed on April 16th last, as already described in these columns. She was a self-made young woman, of gracious personality, who had endeared herself to the staff of *Leslie's Weekly*, of which she was a member, and to every one in the aviation fraternity. Miss Blanche Scott, the only aviatress we have remaining, was flying at the Boston meet at the time of the accident. She did not give up on account of it, but continued to fly every day until the end of the meet.

Destruction of the Airship "Akron"

Vaniman's Career and Tragic End



The airship "Akron" on one of its trial trips maneuvering close to the water.

AMERICA'S only airship vanished in a flash of smoke at 6 38 in the morning of July 2d, and with it perished America's only aeronautic engineer with his crew of four men The accident, although viewed by three thousand spectators along the shore of Atlantic City, will ever remain a mystery, for not a soul aboard the vessel survived. Eye-witnesses of the disaster speak of a wreath of smoke that appeared, followed by a caving in of the gas bag. An instant later there was a loud explosion that burst the envelope, and the car dashed down into the sea, where it fell a heap of wreckage in water a few feet deep.

The cause of the disaster is open to conjecture It seems to be the general opinion that it was due to rapid expansion of gas under the heat of the sun, although it is not clear that there was much variation in temperature while the airship was in flight The "Akron" was brought out at 6 15, and took to the air without mishap Apparently everything was running smoothly and a number of maneuvers were executed successfully. After a time it was seen to rise to a considerable height, and it was apprehended that Mr Vaniman was having difficulty in bringing the dirigible down. Possibly, and this is a mere surmise, Mr. Vaniman attempted to bring the airship down by pumping air ballast into the ballonets. Possibly he had miscalculated the strength of his envelope, or his pressure gages may have been incorrect or else his safety valve may have jammed. At any rate, it is probable that a serious leak developed and that the hydrogen was touched off by the redhot exhaust gases from the engines

When the "Akron" was being built last fall, great secrecy was preserved concerning the fabric employed Every scrap and clipping of the material was carefully preserved and kept from the hands of souvenir seekers. It came out afterward that Mr Vaniman placed great hopes in this fabric, for it had been made many times stronger than the ordinary fabric used in a dirigible balloon He hoped thus to prevent expansion of the balloon with every slight variation in the temperature of the gas and to obviate the necessity of releasing gas when the balloon arose into the rarer atmosphere of higher levels When the "Akron" received its first test in the flight of November 4th, last year, Mr Vaniman found that this principle was correct and he succeeded in making the dirigible rise and fall by subtracting or adding to the air ballast he carried in his ballonets For instance, if he wished the machine to come down, he would pump air into the ballonets, compressing the gas and making the balloon heavier without increasing its displacement His idea then was to pick up water ballast from the ocean in what he called a "hydro levator" Although the flight ended in a mishap, the experiments were successful and led Mr Vaniman to the invention of the "wire wound" dirigible balloon, that is a balloon made of a fabric reinforced with steel wire

A description of this balloon appeared in our issue of February 17th The idea was to use, with the cotton thread, steel piano wire no thicker than the thread, weaving the two together in a loom of special construction. The wires were to be of continuous length from end to end of the balloon and the fabric was to be laid on in two layers, one running longitudinally and the other spirally about the balloon. By placing the wires a tenth of an inch apart in one of the layers and a twentieth of an inch apart in the other, he was able to make a fabric so strong that it would resist a pressure of 52 inches of water against $1\frac{1}{2}$ inches of water in the "Akron," and less than half an inch of water in the ordinary balloon. Thus by making the bag thirty-five times stronger than that of the "Akron" he would be able to prevent it from expanding even though the temperature of the gas within rose fifty Fahrenheit degrees. On an airship of the size of the "Akron," the weight of the steel wire would have added about two and a half tons, but this would have been a small price to pay for the absolute stability obtained. It would then be a simple matter to bring the dirigible down by pumping air into the ballonets and then to raise the dirigible by releasing the air from the ballonets. The task of constructing such a balloon is no small one, and many problems arose, but Mr. Vaniman showed remarkable ingenuity in solving them. We are informed that he had ordered a loom and was about to begin the actual construction of the new balloon at Atlantic City when the disaster occurred.

The "Akron" was the first American-built dirigible balloon to compare favorably with the highly advanced practice in Europe. All our other dirigible balloons have been mere toys in comparison. The Wellman airship was not an American-built vessel, but was first constructed in France for the Arctic expeditions, and then merely reconstructed in this country for the transatlantic venture. The "Akron," however, may be considered the first and only airship worthy the name that this country has ever produced. It was 258 feet long, 47 feet in diameter, and had a capacity of 400,000 cubic feet. It was provided with three engines, two of 100 horse-power and one of 80 horse-power, which were designed to propel the craft at a speed of 30 miles per hour when all three pairs of propellers were operating at the same time. The two after pairs of propellers were arranged to be swung about at such an angle as to drive the airship up or down as desired. In addition to this there were planes fore and aft which could be used for steering the vessel vertically. As in the Wellman airship, the car was built in contact with the under side of the gas bag instead of being separated by a considerable space, as in all other types of non-rigid dirigibles. This served to stiffen the structure, but brought the highly inflammable hydrogen into close proximity with the engines. Possibly this daring design may have been the cause of the disaster.

Melvin Vaniman met his death in the prime of life, at the age of forty-five. He was born at Virden, Ill., near Springfield, on a farm. His father, an Ohio man, was one of the pioneers who opened up that section. The first sixteen or seventeen years of Vaniman's life were spent upon the farm; subsequently he went to college at Mount Morris, near Chicago, and at Valparaiso, Ind. He then took up the study of music at Chicago, and was for a time active on the stage as an opera singer. It was upon these operatic tours that he began to carry a camera with him, which, as events subsequently turned, strangely enough proved to be the first cause of his entering the field of aeronautics.

This opera company with which he was traveling made a western tour to San Francisco and Honolulu and was overtaken by ill fortune, a plague scare having broken out in Honolulu, which so affected the commercial situation that the company was dissolved. Mr. Vaniman, therefore, looked about him for some business opportunity, and his services were engaged by a steamship company, which took him on one of its tours to prepare photographs of the scenery *en route*. In this way Vaniman visited New Zealand. Here he prepared photographs for the New Zealand Tourists' Department, and his collection was of such excellence that it was exhibited at the St. Louis World's Fair, and received a gold medal, the highest award. Vaniman had constructed a special camera for his work, which enabled him to prepare very large, panoramic pictures. It is this camera which, by a peculiar trend of events, proved the first cause of Mr. Vaniman's interest in balloons. In order to obtain his pictures he was forced to seek out elevated points which were often not easy of access, such as the tops of trees, masts and similar inconvenient places. He, therefore, conceived the idea of making use of a captive balloon for his purposes. This plan took him to London, Paris and Rome. The captive balloon, however, still had this inconvenience; it had to be launched from the neighborhood of gas works. An obvious way to overcome this difficulty would have been to employ a dirigible air-craft. Hence, Vaniman, with his resourceful mind, turned his thoughts to the construction of aeroplanes, upon which he worked for some time, finally turning out a machine which proved to be ill-fated, and was completely destroyed in one of the trials in landing.

[...]ieled in Vaniman's life is his introduction to Mr. Wellman, who had just finished his first polar campaign and was preparing for a second. Offers of plans for a dirigible balloon for the second expedition were called for, and Vaniman's designs were the ones chosen and he himself appointed chief engineer. He went north in 1907 and spent the summer building the balloon. Two trips were made with this balloon; the first time the crew was lost in a snowstorm, and landed in a glacier. The second trip was hardly more successful, and was brought to an abrupt and early conclusion by the tearing off of the equilibrator, which in this instance was ballasted with food and provisions for the party. The expedition, therefore, had to be abandoned. Peary's discovery of the North Pole put an end to further attempts at Arctic airship expeditions, and the next venture was the Wellman transatlantic expedition.

The crossing of the Atlantic by airship has seemed such a foolhardy undertaking that the public has been inclined to consider Mr. Vaniman a mere reckless adventurer. He was more seriously taken when he actually made the attempt. The public was quick to grasp the fact that Mr. Vaniman was the moving spirit in this expedition and the engineer to whom all credit for the partial success was due. The attempt was not an utter failure. The "America," as the airship was called, stayed in the air 71½ hours, establishing a record for dirigible balloons, and covered 1,008 miles, which was also a record. The equilibrator, or floating drag, retarded the airship to such an extent that it could not keep up with the winds that were carrying it across the Atlantic, and yet without the equilibrator the airship surely would have been lost on the third day out. As was stated in the SCIENTIFIC AMERICAN at the time, when the "America" was abandoned it was structurally just as sound as when it put out from Atlantic City, except that one of the propellers was disabled.

When a member of the editorial staff of the SCIENTIFIC AMERICAN visited Mr. Vaniman after his rescue from the "America," and questioned him on the object of such a venture, Mr. Vaniman was careful to explain that it was not from choice that he had undertaken the trip. He felt that the dirigible balloon was being entirely neglected in this country, and that it ought to receive far more attention than the aeroplane. He knew that only by accomplishing something of a startling nature could he arouse his countrymen to the value of this form of aerial navigation, and he stated that if he could arouse equal interest in some other way, he would rather do so. He realized the hazards of navigation in a dirigible balloon, but was sure that they would yield to study and experiment. When the idea of wired fabric occurred to him he was confident that the problem of safety in the air was solved at last. He never made extravagant claims for aerial navigation. He did not believe that the dirigible balloon could ever be used for transporting mail or express matter or for carrying people from place to place on scheduled time, since so much depends upon the direction of the wind. However, he did expect to see the time when stable wire-reinforced balloons would be used for pleasure trips and vacation tours. It is a pity that his life was not spared to complete this new balloon and demonstrate its usefulness. We are inclined to believe with him that it held out unusual promise of success, and unfortunately there appears to be no one else in this country with the ability and experience to carry on his work.

Radio-activity of Human Organs

DR. COARNS, of the Heidelberg Institute for the Study of Cancer, has succeeded in obtaining experimental evidence of the radio-activity of various human organs. The first experiments were made by allowing the organic matter to act through a wire grating, on a photographic plate wrapped in black paper. Faint radiographs were obtained by twenty-four hours' exposure, the strongest action being exerted by the substance of the brain. In order to prove that the observed effects were really produced by radio-activity of the organic substance, portions of the brain, heart, liver, spleen and lungs of twelve cadavers were incinerated and their radio-activity was tested with Becker's emanometer, by measuring the rate at which the electrometer of the apparatus lost its charge under the influence of the incinerated substance. In most cases, one gramme of the substance produced more or less conductivity in the air. The brain was found to be the most strongly radio-active organ. A surprisingly great effect was produced by the incinerated brain of a person who in life had drunk large quantities of radio-active water for the alleviation of abdominal pains. The kidneys and the spleen were uniformly found to be the least radio-active of the organs examined, and the liver and the heart also showed little radio-activity. In two cases the substance of the lungs was tested, and was found to possess a comparatively high radio-activity. The number of measurements is too small to allow definite conclusions to be drawn.

The soil receiving a heavy application of lime required for alfalfa growth.

ALFALFA, perhaps the oldest of all our cultivated forage or hay plants, has had a history scarcely less interesting than that of the many nations which have utilized it. Such nations have prospered almost in direct proportion to the extent to which they have used it. The name "alfalfa" comes from the Arabs and means "the best fodder," and in fact it appears to have originated in Media or in some adjacent country, as the folklore tales from lands on different sides of this area point toward Media as the place whence it came. Although in its original state it must have had a narrow range of adaptability to varying climatic and soil conditions it has by successive stages come to be adapted to portions of every continent. Even in this country it grows below the sea level in southern California, where the climate is among the hottest in the world. In Colorado it may be seen in full vigor at altitudes above 8,500 feet. In latitude it is equally cosmopolitan and may be found growing from Mexico to Canada as well as in tropical America. The eastern half of the United States has presented a serious combination of circumstances working against its successful production. A brief survey of its early history and migrations may assist in explaining some of the reasons why the culture of alfalfa in the East has met with so many difficulties and why so many points must be safeguarded to assure success.

Alfalfa in Ancient Times.

The wars of the Persian Invasion of Greece took it to the latter country about 590 B. C., it being the custom for the advance emissaries to precede the army and to plant fields for the sustenance of the herds which helped support the invading hosts. From Greece it advanced to Italy and Spain by successive stages and was taken to Old Mexico by the Spaniards about 1519 A. D. From here it was carried to South America and later (1854) entered California through the Golden Gate at the time of the activities incident to the discovery of gold in that State. Thence it spread over the irrigated sections and more recently has continued its march eastward until now it is by far the most important forage crop of such States as Nebraska and Kansas, the latter having approximately a million acres as compared with a very few thousand two decades ago.

The eastern march of alfalfa halted, however, when it encountered the humid belt beginning with Missouri and extending eastward to the Atlantic ocean. Alfalfa was developed under scorching suns and in sections almost devoid of natural rainfall and the unnatural conditions presented by a country where the rainfall is at all excessive constitute a great handicap to its successful production. The increased rainfall causes most soils to be poorly drained and these are usually sour or "acid" in character. Both the poor drainage and acid condition of the soil prove harmful to the plants. This is by reason of the prevention of the growth of the nitrogen-gathering bacteria which are so essential to the welfare of the alfalfa plant itself and which enable the roots to accumulate vast stores of the costly nitrogen from the air, free of charge to the farmer. As has been said these bacteria not only work for nothing and board themselves, but they actually pay something for the privilege of living. They must, however, have the proper soil conditions and these are not naturally present on the ordinary farm in the Eastern States.

Requirements of Alfalfa.

Alfalfa requires a deep, fertile, well drained, well limed, thoroughly inoculated, acid-free soil. This list of requirements is long, but it means a great deal to the ordinary farmer, who usually is unable to immediately provide these conditions for alfalfa. In order to emphasize the necessity of each of these, it is necessary to treat them somewhat in detail.

A deep soil is necessary by reason of the great root development which the alfalfa plant makes. In the West the plants have been known to send down long roots for more than 30 feet into the deep, friable, alluvial soils. It is not able to make its normal growth and compete with the surface-feeding weeds if there is not present a soil sufficiently deep for its roots to penetrate and draw up the hidden stores of plant food which are necessary for the numerous crops of nutritious forage and which are out of the reach of the less deeply rooting plants. At least four feet of good soil is usually necessary unless the underlying formation be limestone, in which case, three feet has been found to suffice. The plants will, however, utilize the ground to a much greater depth if opportunity is presented for them to do so.

A fertile ground is necessary, since the hay it produces is among the richest we have and calls for the extraction from the soil of large amounts of plant food. It is a mistake to think that because it is a legume and has the power of adding nitrates to the soil that it can be seeded on land poor in the other essential elements of fertility. It cannot add phosphoric acid or potash to the soil on which it grows; and yet it requires large quantities of these elements in order to produce paying crops of hay. This fertility may be brought into the soil by the use of green manures, commercial fertilizers or by the application of a liberal dressing of barnyard manure. The last method has been found to be usually the most satisfactory as, apparently, the manure offers the conditions required by the bacteria which live on the roots of the alfalfa.

A well-drained soil is essential as the roots can not stand lack of drainage, nor can the bacteria which ordinarily live on its roots, exist in the absence of a well aerated soil.

Liming is necessary on all soils deficient in this mineral, as in the presence of acid conditions neither the bacteria nor the alfalfa itself can succeed.

It is also necessary to have the soil thoroughly inoculated with the nitrogen-fixing germs in order that each plant may be well provided with these organisms for abstracting the nitrogen from the air and converting it into a form available to the alfalfa plant.

A weed-free soil is desirable, especially a soil free from perennial weeds which cannot be eradicated by mowing. The annual weeds may be best avoided by seeding the alfalfa in the late summer which allows the plants to attain a fair size before winter. The stand of well grown plants the following spring will do much toward preventing the development of any freshly germinated weeds. It would, therefore, appear that it is possible to raise alfalfa in many parts of the Eastern States, in case proper attention is given to the selection and preparation of the ground. A number of years may be required to develop a poor field to the proper richness to hold the stand of alfalfa.

On account of the rather peculiar and exacting requirements, respecting soil and fertilizers, as well as the high price of the seed, alfalfa is not what may be called a "poor man's crop;" neither is it a crop for a run-down or unfertile farm. Its present uncertainty on many types of soil should also retard the man of limited financial means from going into its production on an extensive scale at first.

It is suggested that an experimental acre be established and divided into a number of subdivisions. Each subdivision should be given a different treatment as regards fertilizing, liming, time of seeding, rate of seeding and preparation of the soil. Each one of these plots will answer at least one question regarding the effect of a particular method of treatment. In this way the information which would otherwise require a number of seasons to procure, can be obtained at the end of the first year. The treatment proving best adapted to the particular conditions present can be applied to a larger area the succeeding season. In this way alfalfa can, if shown to be adapted to an individual farm, become established on that farm at the least possible risk to the owner or worker of the ground. The first seeding will usually furnish an abundance of soil for inoculating the subsequent seedings of alfalfa. This utilization of soil from one's own farm avoids the danger of introducing weeds and plant diseases from other sections.

Enemies of Alfalfa.

Weeds as might be expected constitute, perhaps, the worst enemy of alfalfa, and among these crab grass probably ranks first. Alfalfa does not make a vigorous growth during the midsummer in most parts of the East, and it is during this season of the year that the crab grass and other weeds make their most luxuriant progress. Unless there is an abundance of plant food in the soil to produce a luxuriant development of alfalfa the plants are apt to become soon reduced in vitality as to be unable to resist the crowding of the weedy grasses; so much so, in fact, that they may not be able to make a sufficient recovery for the succeeding season's growth. The weeds must be controlled. This is best accomplish by seeding the alfalfa in the late summer or early fall on land that is comparatively free from weeds and has been rendered even more nearly free from weeds by repeated harrowings; and, second, by maintaining the alfalfa in a sufficiently vigorous condition so that the weeds will be unable to obtain a foothold in the field. In actual practice it is seldom possible in the East to hold a stand of alfalfa for more than three or four years owing to the vigorous incursions of the more aggressive weeds. On limestone soils blue grass is very apt to crowd out the alfalfa plants. On other soils crab grass seems to take front rank among the alfalfa enemies. Plant diseases are always preying on alfalfa. These are especially troublesome when the vigor of the alfalfa is reduced by growing in soil not perfectly adapted to it.

Spring Seeding Versus Late Summer Seeding.

Much money and effort has been and is still being wasted by seeding alfalfa at the wrong season of the year. Many experiments have indicated that spring seeding, except in the extreme North, is a dangerous practice. The young plants are of a slow growth at first and as a consequence are easily crowded out by the more aggressive weeds in the late spring and early summer. The seeding should take place the middle of August in the latitude of Maryland and Virginia. Every hundred miles north calls for the seeding to take place one week earlier, while for every hundred miles south the seeding should be delayed for one week. If the land has been plowed and frequently harrowed for six weeks or two months before seeding, the plants will frequently produce a growth of ten to twelve inches before cold weather. This comparatively heavy

growth of alfalfa checks the growth of the winter growing weeds while the alfalfa plants are of sufficient size to make a rapid growth the next spring, and under ordinary circumstances will keep ahead of the weeds until the first crop is harvested. It is not usually possible north of the Potomac or Ohio rivers to turn under grain stubble in time for the middle of August seeding of alfalfa. A crop of early potatoes, however, can usually be removed in ample time for the seeding of the alfalfa since the ground does not require replowing and no time is lost in waiting for the ground to settle sufficiently to permit planting.

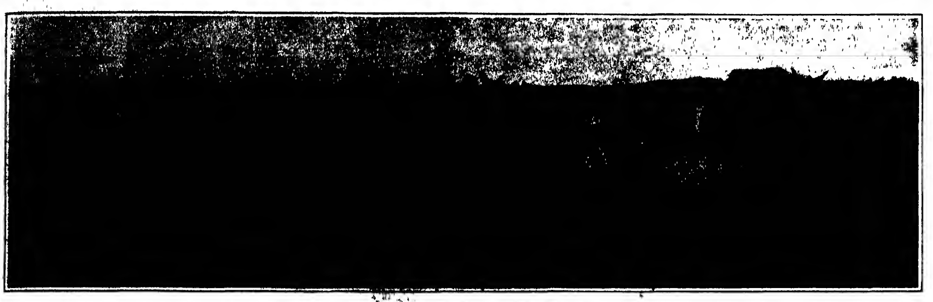
Harvesting the Alfalfa Crop.

Alfalfa gives several cuttings during a season. Every cutting should be made just as the crown of basal buds are starting the growth of the next crop. This will usually happen just as the plants are coming to bloom, at which time they range from 14 to 40 inches in height. The hay should be cured without shattering any more of the leaves than is absolutely necessary. The leaves are by far the richest part of the feed and every effort should be made to retain them. The hay is raked into windrows as soon as the leaves are well wilted and before they get so dry as to shatter. The hay should lie in the windrow until the leaves are dry and the stems still green, when it should be placed in shocks and allowed to cure before being placed in the barn or stacked.

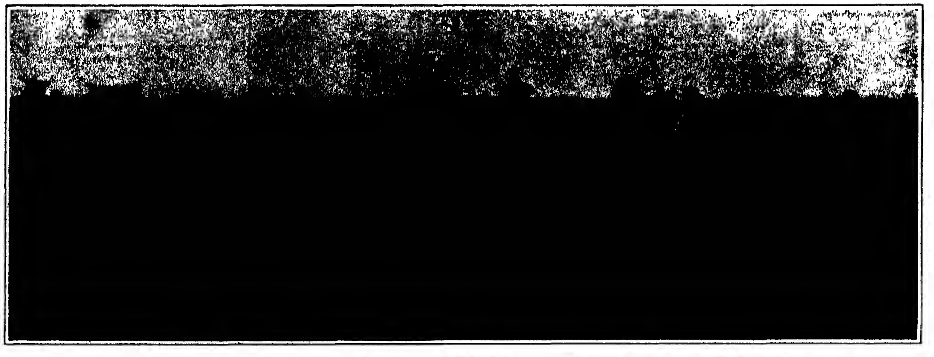
Value of Alfalfa for the Dairyman.

Alfalfa is a friend of the dairy farmer by reason of the marked effect of alfalfa hay on the production of both milk and butter, and also by reason of the excellent effect of the manure from the cow stables upon the growth of this really wonderful forage plant. It is for dairy farms especially that this crop is recommended in the Eastern States. Here, with an abundance of good barnyard or stable manure, the fertilizing bills are greatly reduced, while the cost of concentrates, which usually eat into the profits of the dairy farmer, is reduced to a minimum. With plenty of alfalfa hay for feed it is usually unnecessary to feed any of the high-priced concentrates in order to maintain a profitable flow of milk throughout the year.

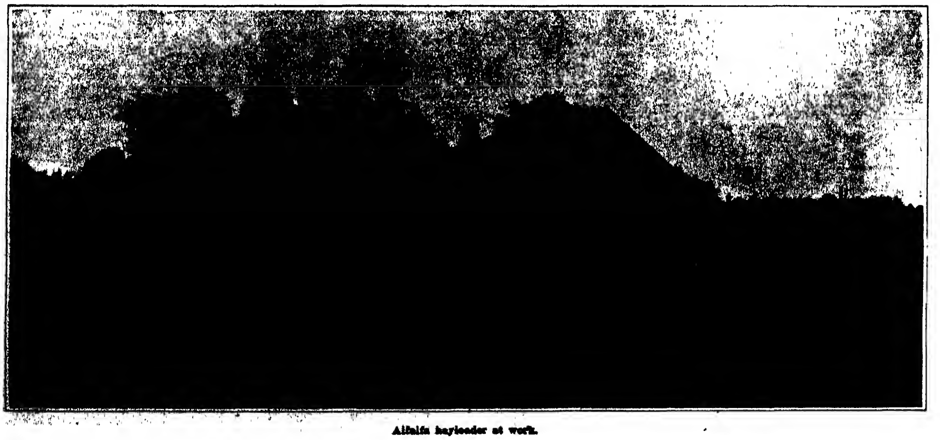
The following ten commandments regarding the culture of alfalfa are important for the prospective alfalfa



Mowing alfalfa in a one hundred-acre field on a Virginia farm.



Inoculation is necessary. Here the harrows cover the soil from some old alfalfa field before the sun's rays can harm the germs.



Alfalfa hayloader at work.

grower to consider. Don't fail to provide for ample inoculation; soil from a healthy weed-free alfalfa field is best. Don't sow poor or weedy seed. Don't sow on a weedy soil. Don't sow on any but a sweet, well limed soil. Don't sow on poorly drained soil. Don't sow on any but a finely prepared, well-settled seed bed. Don't pasture the first or second year. Don't lose the leaves, they constitute the best part of the hay. Don't seed a large acreage to begin with. Experiment on a small area first. Don't give up. Many prominent alfalfa growers finally succeeded only after many failures.

Pedesis in the Metal Uranium

RECENT discoveries in regard to the movements of the alpha particle in radioactive substances have awakened a new interest in an old phenomenon, pedesis, or the Brownian movement. In the pollen grains of plants there are fine granular particles called *forilla* which are set free when the pollen is crushed, and under a high power microscope they exhibit a movement which originally was believed to be analogous to the motions of the spermatozoa of animals.

But in 1827 Dr. Robert Brown observed that many inorganic substances in a fine state of trituration similarly behave.

The movement is chiefly of an oscillatory nature, but the particles also rotate backward and forward, on their axes, and even dart above the field with a rapidity depending, of course, upon the power of the objective. Pumice stone, kaolin, gamboge and finely divided clays show the phenomenon very well, but they must be finely powdered, preferably in an agate mortar. Particles greater in diameter than 1/5500 of an inch are inactive, and it may be said that as a rule, and other things being equal, the finer the particles the more distinct the movement, which is about 1/5000 of an inch at each bound. Of all substances, and the writer has tried hundreds, the metal uranium shows the movement most distinctly, and in a manner almost spectacular. Pure uranium should be used, and pounded in an agate mortar for 15 or 20 minutes, or at least until many of the particles are reduced in diameter from 1/10,000 to 1/20,000 of an inch. Put on a slide a quantity of the powdered material, equal in bulk to a mass 3 or 4 times the head of a pin, add a drop of distilled water with a trace of gum arabic, and observe with a 1/12 oil immersion objective. The whole field seems to quiver with life, and the finer particles dart from point to point with a motion strikingly analogous to that displayed by many micro-organisms.

When the film of the material is of proper thickness and the particles sufficiently reduced in diameter the phenomenon is beheld in a perfect *abandon* of color—the reds and blues being of metallic brilliancy.

The result will well repay one for the effort expended in reproducing this experiment, and, once seen, it can scarcely be forgotten.

The Utilization of Atmospheric Nitrogen

THE importance of nitrogenous compounds to the agricultural and industrial interests of Europe and America has prompted the Bureau of Manufactures to issue a monograph on the subject of utilizing atmospheric nitrogen in the production of such compounds. The nitrogen problem, one of the most pressing of the twentieth century, is unique from the fact that the material is unlimited. The atmospheric nitrogen above one square mile of land, amounting to about 22,000,000 tons, is equivalent to what the world would require in the next fifty years at the present rate of consumption. The problem is to utilize this nitrogen economically, and thus free the world from its dependence on the nitrate deposits of Chile, which are not particularly extensive and are likely to be exhausted at a comparatively early date. Remarkable results have been obtained in Norway by means of electric furnaces in which atmospheric nitrogen is oxidized to the form of nitric oxide, which is used in making calcium nitrate, or Norway saltpeter. This Norwegian product is already an important rival of Chile saltpeter, but as the success of the process depends upon a very cheap supply of electricity it will probably not be used to any great extent in the United States until the furnaces have been made more efficient. Cyanamide, another nitrogenous fertilizer of growing importance, is being manufactured in America and the industry should prove successful, as the production in this country of the calcium carbide required by the process is second only to that of Norway. The monograph describes in detail the results obtained by the leading European chemists in their efforts to increase the supply of nitrogenous compounds, and the commercial as well as the technical aspects of the new industry are dealt with at length. The author, Thomas H. Norton, consul at Chemnitz, Germany, on detail as commercial agent of the Department of Commerce and Labor, states in conclusion that the achievements of applied chemistry make it possible for American industry and agriculture to face with confidence the threatened exhaustion of the nitrate deposits of Chile.

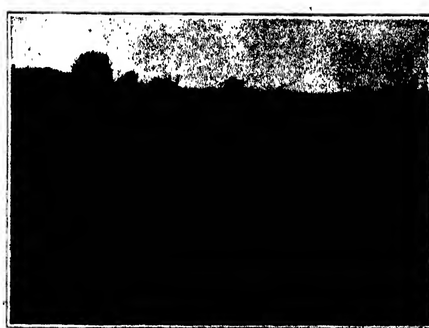
The use of large side delivery rakes leaves the fresh cut alfalfa in shape for the hayloaders.



Removing soil from an old field for use in inoculating a new one.

Open-air Schools of Paris

IN the schools of Paris and other large cities the statistics show that there are on the average 15 per cent affected with tuberculosis, and although this may yet be in the latent state there is none the less a considerable danger for these persons for the future. Open-air schools are advocated for preventing the disease, and Messrs. Parmentier and Bernheim treated the question at the recent Tuberculosis Congress, stating that children so affected had the greatest benefit from their stay in such schools without suffering any drawback to their instruction. In the suburbs of Berlin a method of this kind is carried out in schools where the pupils are not lodged in the buildings. A type of boarding school is found in the suburbs of Paris, and the children are first examined so as to find out how long a time of stay will be of benefit to them. They are divided into groups according to their condition, and are also treated for defects in hearing or in the respiratory passages. The main treatment is a rational method in which open-air work and physical exercise play the most important part. Figures show that the results are excellent, and among the 800 pupils passing through the Vesinet school for the last two years, a great number starting from very bad health conditions received great benefit from even a few weeks stay in the open-air school.

Uses of Seaweed

SOME interesting facts about seaweeds which are used as food or for producing vegetable gelatines or glues, are brought out by Messrs. Perrot and Gatin in the annals of the French Oceanographic Institute. Seaweeds are not much used in Europe except for alkalies or iodine preparation. In the north coast regions of France the seaweed is used by the peasants as a manure upon the fields. Medical uses can be mentioned, and the variety called Iceland moss is collected in Brittany to a considerable extent, this reaching 20 tons of dry seaweed in 1904. One variety of seaweed is a very good vermifuge, and is extensively used for this purpose in Corsica. On account of the iodine which they contain, some seaweeds are remedies against goitre and scrofula. As to food uses, this seems to be limited to the Brittany region and only the poorer population consumes it. Although limited in Europe, the use of seaweeds as food is widespread in the extreme Orient. In Japan, edible seaweed is prepared in a number of ways and it is much cultivated. Iodine is not manufactured in that country at present. One use is for preparing agar-agar, glues and vegetable gums. Seeing that the gelatines from this source are scarcely nutritious, the authors explain their extensive use by the manner of living, and as the population consumes great quantities of fish and rice it is thought that the gelatinous substances aid in digestion and in the intestinal functions. It is valuable for alimentation and export.

Wholesome Water in the Country

The Dangers of Pollution and How They May Be Avoided

By Frederick H. Billings, the Associate Professor of Bacteriology at the University of Kansas

[PROF. FREDERICK H. BILLINGS is a man of considerable experience in matters relating to water supplies, this having been a part of his work in Kansas. He has been professor of botany and bacteriology in the University of Louisiana, 1901 to 1907, and associate professor of cryptogamic botany and bacteriology at the University of Kansas, 1907, and at the coming season is to be head of this department. He received the degree A.B. at Leland Stanford University, 1896; A.M., Harvard, 1897; and Ph.D., Munich, 1901. He has been bacteriologist to the Department of Water and Sewage of the Kansas State Board of Health. Much of his investigation and work have been along the lines of milk and butter. In addition to his regular studies Dr. Billings has taken two summer courses in bacteriology at the Harvard Medical School and one in dairying at the University of Wisconsin. At present he is at the Massachusetts Institute of Technology, where because of his high standing the courtesies of the laboratories and lectures are tendered to him. On his return to Kansas, besides his academic duties he will assume high responsibilities in the care of the State Analysis of Water.—EDITOR.]

From very remote times, a good water supply has been considered one of the greatest blessings since the fight of Isaac's herdsmen for the wells of Gerar down to present-day irrigation. Its possession has been subject to contention. Possibly good water was of more frequent occurrence among patriarchal tribes in their nomadic life than in our modern settled habitations. At all events, the growth of civilization has pressed upon us the problem of combating the contamination of water supply.

How the Quality of Water is Judged.

The quality of water has generally been judged by its degree of sparkle, of turbidity, of temperature, and, since the introduction of soap, of hardness. These standards have their value, but they are considered by sanitarians to be superficial criteria for determining wholesomeness. Water may be hard, warm, flat and turbid and yet be safe to drink. It may also be soft, cold, clear and sparkling, and still carry infection. Wholesomeness depends upon comparative absence of salts and organic matter, deleterious to health. Injurious salts, while inducing disturbances of a more or less discomforting nature, even causing permanent injury if long-continued, do not create such serious consequences as polluting organic matter, especially if this takes the form of pathogenic micro-organisms.

It is believed that decaying animal refuse, draining from garbage heaps, barnyards, piggeries, manured fields, cesspools, privy-vaults, and the like, may occasion sickness when it finds its way into a water supply; but an equal degree of danger does not exist in all of these sources of filth. Animal manure and garbage are in a class by themselves in that they are not liable to contain the germs of disease that would produce infection in man through water. Cesspools and privy-vaults are in another class, since they are open to infection by bacteria particularly pathogenic for man. Water containing such germs assumes its most menacing aspect, especially if under the insidious guise of a cold and sparkling beverage.

It would be desirable, of course, if every source of water supply could be examined by a sanitary bacteriologist in order to determine the liability of contamination; but so huge is the task that the solution of the question in many instances must be left to the intelligent judgment of the resident himself. Bacteriological analysis, moreover, though the most reliable we have, may fail at times to tell the whole truth, especially if too infrequently made. Such analysis is concerned usually with the detection of the colon bacillus, an intestinal organism indicating fecal contamination, and condemning water by its presence, because of occasional association with infectious microbes of the same habitat. Of such, one kind is the well-known *Bacillus typhosus*, the source of typhoid fever, which, in this country, is the principal water-borne disease. Its germ is found in the intestines of typhoid patients, of convalescents, and for a while, of those who have fully recovered. It is believed, also, to occur sometimes in healthy people who have never been known to have had the fever. The excrement of all such individuals is laden with the specific organisms, and becomes exceedingly dangerous to others, if its disposal is improperly cared for. In rural districts, it usually finds lodgment in privy-vaults, cesspools, or on the ground, from any of which, permeations or washings containing living bacilli may find their way into some water supply. As the specific germ of typhoid is known to emanate only from infected persons, who constitute but a small percentage of the average community, the majority of country water supplies, even though otherwise contaminated, would be incapable of creating an outbreak of this particular disease. Typhoid, moreover, is not limited to water as a means of transmission, for contact and infected food play their part. But, after all has been said, it still remains true that water has often been a serious source of infection, causing numerous epidemics and disastrous loss of life.

The Water Supply of the Average Man.

The average man, when confronted with an adverse analysis of his water supply, is liable to be surprised, declaring that it is the best in the country, and that it has been used for years without producing illness. Granting that he be right, immunity in the past is no guaranty, unfortunately, for the present or future. In his case, some connection has evidently become established between well and outhouse or cesspool, and apparently he has not happened to harbor a typhoid-infected person on the premises. There is nothing needed now but the carrier of the specific organism to begin the trouble.

Rural water supply is generally obtained from springs, wells or cisterns. From a sanitary standpoint, springs and deep wells—deep in the sense of penetrating below the first impervious stratum—are the most reliable sources. The usual excellence of these, and, in fact, of all good ground water, is largely due to the filtering property of the soil. Springs, especially those flowing through fissures, and deep wells reap the benefit of prolonged filtration through earth. But both may be subject to contamination, particularly springs, which are often open to surface washings from sewage-drains, and the like, located farther up the slope. Hence it is advisable to inspect the watershed above a spring; also, to guard it from the surface washings by a wall or ditch.

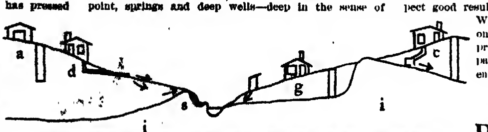


Diagram illustrating relations between water supply and sewage disposal in the country.

a, Stable with adjacent well, liable to contamination from surface washings and ground seepage. *d*, House with sewage drain to the surface. *s*, Spring in danger of contamination from drain just above. *g*, House with properly placed well and outhouse. *c*, House with cesspool, apparently properly placed on lower ground, but because of adjacent formation, the well is liable to contamination. The well at house *g* is in little danger from the cesspool because of the intervening impervious stratum of earth or rock (*i*, *i*), an impervious stratum whose relations to sanitation are important

The Danger that Lurks in a Badly Located Well.

Driven wells and dug wells reach only to ground water, differing in this respect from many springs and all deep wells. Their shallowness brings them at times into proximity to drainage from privy-vaults, cesspools or leaky drains, and anyone sinking a well near these sources of filth must rely upon the filtering action of the soil to remove pathogenic bacteria. The filtering efficiency of the soil, in serving to protect wells from contamination, depends upon such factors as the extent and the nature of the intervening soil and also upon direction of ground-water drainage. The distance that should exist between a well and a source of pollution is, because of these, so variable, that probably no definite rule would be trustworthy in all localities other than the greater the distance the better. Nevertheless, from experiments conducted by the writer for the purpose, one hundred feet was found to be the least distance compatible with safety. A less distance would doubtless be safe in certain instances, but greater risk would be incurred of encountering or establishing direct connection through cracks or passages in the subsoil. Pumping a well, moreover, lowers the water table about it, causing drainage from adjacent soil toward itself as a center. Contaminating material within the radius of this flow would thereby be drawn toward the water supply.

The course of ground-water drainage toward its natural outlet affects the liability of a well to pollution. While it usually follows the direction of the superficial slope, it may take a different route, owing to peculiar subsoil formation. Therefore, while it is better to locate a well on higher ground than a cesspool or outhouse, it is also prudent to have a safe distance intervening as an additional precaution.

Driven and dug wells, though similar underground in point of possibility of contamination, differ materially when danger of surface pollution is considered. Driven wells are comparatively secure, while dug wells, open above, or covered with loose boards, through which filth may sift, or else with low and defective curbs, invite every sort of objectionable material that may fall or wash in. For this reason, dug wells are responsible for a greater extent of typhoid infection than any other source of rural water supply.

Cisterns, if underground and near leaky drains, cesspools, and the like, are exposed to conditions similar to wells, when they are not water-tight, and few of them are. In the South, where mild winters prevail, cisterns are usually above ground and are, therefore, not subject to soil pollution. Both kinds, however, are filled by roof washings, which, if not allowed to run to waste at the beginning of a storm, may carry refuse of an undesirable though not infectious kind. Cistern water has been known to be a vehicle for typhoid, but it is not so probable a source of danger in this respect as a dug well. The care with regard to location, to entrance water, and to cleansing, should insure good water from a cistern.

Finally, it may be said that the maintenance of wholesome water supply of any kind requires constant watching. To dig a hole to water anywhere and expect good results forever afterward, is unreasonable. With the exercise of common sense, based on the knowledge of ordinary sanitary principles, a person should live in comparative security from water-borne disease.

Plants and Tobacco Smoke

PROF. MOLISCH, the plant physiologist of the University of Prague, has shown in some of his earlier work that large numbers of micro-organisms, plants as well as animals, and the seedlings of higher plants are extremely sensitive to the influence of tobacco smoke, some being even killed thereby. Many of the deleterious effects experienced by plants living in laboratories were formerly attributed to the small quantities of illuminating gas which frequently vitiates the atmosphere of such rooms, but Molisch's experiments left no room for doubt that it is really the tobacco smoke that does the harm. His pictures showing the growth of pea and vetch seedlings in the presence and in the absence of tobacco smoke are very striking.

In his more recent experiments he used older plants of various species, including species of spiderwort, *Echeveria*, *Eupatorium*, *Selaginella*, and others. None of these plants showed any ill effects from the treatment, although exposed for a long time to an atmosphere filled with tobacco smoke. Other plants, however, responded in various striking ways.

Bœhmeria utilis and *Splitgerbera biloba* changed their manner of growth. When placed in a large bell jar and a few puffs of smoke from a cigar or cigarette were blown in, the leaves of these plants, ordinarily growing at right angles to the stem, that is, in a horizontal position, began to turn on their stalks, in the course of from 24 to 48 hours, until they were in a vertical plane. In the case of the *Bœhmeria* they continued their rotations beyond this point, describing a spiral. Similar disturbances were produced upon these two plants by illuminating gas. But other plants used in the experiments showed similar effects of tobacco smoke, but did not respond to the illuminating gas.

Earlier experiments showed that various narcotics provoke abnormal development of the breathing holes on the shoot of the potato. Experiments with tobacco smoke on the potato and on other plants led to the same results, often with the accumulation of masses of liquid under the swollen areas.

In some plants of the bean family the tobacco smoke caused the leaves to drop off in a very short time. The sensitive plant (*Mimosa pudica*) and the black locust (*Robinia pseudacacia*) and others lost all or nearly all of their leaves in from 24 to 48 hours after being placed in an atmosphere containing tobacco smoke. To a smaller degree smoke from wood and paper, and illuminating gas produced similar results. The fumes of nicotine had very little influence.

Insects and Disease

The Mechanical and Biological Methods of Transmission

By W. C. Rucker, M.S., M.D., Assistant Surgeon-General, U. S. Public Health and Marine Hospital Service, Washington, D. C.

[*MAN in the Stone Age was obliged to carry on an unceasing battle for existence with ferocious mammals and venomous serpents. Happily those days have passed, but to-day the struggle to live is no less acute, but it has resolved itself into a combat with the lower forms of vegetable and animal life. Insects as the intermediary vehicles in the transmission of disease are a menace to the present and future welfare of the race, and if we would preserve our physical integrity we must live in insect-free surroundings. The field for research into this problem is a wide one, and as yet has only been touched in its most apparent phases. The future must see a combined effort on the part of the entomologist, the physician and the sanitarian if we would conquer these dangerous and annoying pests. The burden cannot be borne entirely, however, by men of science; the citizen and man of affairs must do his part in the application of the discoveries which mean so much to the individual and the race*.—EDITOR.]

The idea of the transmission of disease-producing organisms to man by insects is no new thing. For example, the Bible (Exodus 8 and 9) tells how the unusual prevalence of flies and lice was followed by a murrain of cattle and an epidemic of boils. It is only within recent years, however, that scientific workers have been able by the use of the microscope and other instruments of precision to trace the course of the seeds of disease through the body of the insect and into the body of man.

In order intelligently to approach the consideration of this latter day scientific development, it is necessary to understand the way in which the insect acquires the organisms which produce disease, the changes which these organisms undergo within the body of the insect, the way in which they are introduced into the human body, and the developmental changes which take place in them in the course of their attack upon the human victim.

Broadly speaking, there are two general methods by which this process is accomplished. These are the mechanical and biological methods. In the mechanical transmission of disease germs by insects, we find the insect in question coming accidentally in contact with disease-producing organisms and carrying them into the body of man either directly by biting, or indirectly as by infecting food. It is not necessary for the life of the germ in question that it be carried by any particular insect. No developmental changes, which are of any account, occur in the organisms during the period of this transportation to man, and therefore we may find many different insects of totally different habits acting as vectors for a given germ. As an example of the mechanical method of transmission, in contradistinction to the biological method of transmission, we have the carriage of typhoid bacilli from infected excrement by flies. In this instance the fly smears his feet, proboscis and wings with the discharges of a person who has typhoid fever, and then alighting on foodstuffs there deposits the germs to be taken by some unsuspecting person. In this instance no change whatever has been undergone by the bacilli, and they could quite as well have been carried by a cockroach which might similarly infect food. In the case of the transmission of tuberculosis by flies, the mechanical method of transmission still obtains, but it has been determined by experiments that, in this instance, there may be an actual multiplication of the tubercle bacilli within the body of the fly and that living bacilli may be discharged in the fly's excreta. In the case of the transmission of plague by the flea, another example of mechanical transmission, it is not necessary that any particular species of flea act as the vehicle. The flea becomes infected by biting an animal which has the germs of plague in its blood. The flea imbibes this pest-laden material and subsequently bites a human being. It is not by the act of biting, however, that it transmits the germs of this disease. The flea has the habit of depositing his excrement at the time of biting. A person who is bitten naturally suffers some irritation and rubs or scratches the bitten place. In doing this the germs of the disease are rubbed into the skin, which they penetrate and thus gain entrance to the body.

The transmission of malaria is a typical example of the biological transmission of a disease-producing parasite. The organism of malaria is a small unicellular animal which grows and develops in the red blood cells of man and in the various tissues of the *Anopheles* species of mosquito. This germ has two complete developmental cycles, one in the blood of man and the other in the body of the female *Anopheles*. The human cycle is the asexual cycle, development taking place without conjugation of the male and female elements. The mosquito cycle, on the contrary, is a sexual cycle, conjugation taking place. It is thus seen that for the perpetuation of this organism it is necessary that it alternate between the body of man and the body of the mosquito. *Let it be supposed that a female Anopheles* (males do not bite) bites a person in whose blood the *Hemamoebae malariae* exist. When this blood is taken into the stomach of the mosquito, the two different forms of the germ corresponding to the male and the female elements undergo a series of changes, and conjugation takes place. The result of this union penetrates the wall of the mosquito's stomach, on the exterior of which is produced a small cyst or blister. Development continues within this cyst, and many sharp spindle-shaped immature forms are taken up by the blood stream and carried to the salivary glands of the mosquito. When this mosquito bites another person it expectorates through the siphon which is used for extracting blood. It is said that the reason for this act is a desire to thin the blood which is to be extracted. As the saliva is drawn from the gland in which the immature forms are lodged it is infected with them. These bodies thus introduced into the human system enter the red blood cells, and the person becomes infected with malaria. In yellow fever, although the appearance of the causative germ is not known, thanks to the preliminary work of Finlay and Carter and the conclusive experiments of Reed and his associates, the length of the developmental cycle in man and in the *Stegomyia* mosquito is definitely known.

Flies may carry the germs of typhoid fever, cholera, dysentery and tuberculosis, and it may be that these ubiquitous household pests may carry other diseases as well. Two varieties are commonly met with in this country, the *Musca domestica* or common house fly and the stable fly or *Stomoxys calcitrans*. Both are bred in manure, and it has been recently estimated that each pair of flies surviving the winter may be the ancestors of eight million living flies during the summer. Flies are omnivorous in their habits, and will eat filth of almost any kind. The first thing to do to get rid of flies is to exclude them from the home of man, and this may be accomplished by the use of screens, both as to doors and windows. These should fit accurately and should be constructed of some permanent non-corrosive material, such as bronze wire. Inasmuch as screens are also intended to exclude mosquitoes, the screening should have a mesh of at least eighteen to the inch. After this has been done, it remains to destroy the breeding places of the flies and get rid of those things which attract them. Stables or other out-buildings should be well screened. The manure should be stored in water-tight metal lined boxes which are emptied at least once in ten days. The frequent addition of chlorinated lime or soaking with kerosene oil will also prevent breeding. Stables should be maintained in a cleanly condition. The unsanitary garbage can is the fly's paradise. The water-tight metal garbage can with a tight-fitting lid will feed no flies. If the remainder of the premises is kept clean, few of these pests will be seen therein.

Mosquitoes of different species are known to transmit malaria, yellow fever, dengue ("break-bone fever") and filiariasis (the elephantiasis which is seen in the tropics). So far as is known, the mosquito type of transmission is biological. More than this, it is also obligatory, i. e., one general species only is concerned in the transmission of a certain disease. Since each of these species has its own particular habits, the methods to be used in destroying them should take into account these differences. In general, it may be said that mosquitoes do not travel far, and live and die on the premises on which they are bred. The yellow fever mosquito *Stegomyia calopus* is a small black and white insect breeding by preference in fresh, clean, quiet water. It is very generally distributed in a belt which extends around the world forty degrees on each side of the equator. In order that this mosquito may become infected, it is necessary that it bite a patient in the first three days of his illness. After having thus become infected, a period varying from eleven to twenty days (usually fourteen days, but depending upon the atmospheric temperature) must elapse before it may retransmit the disease. From that time to the end of its life, which is frequently as long as one hundred days, this mosquito may continue to distribute the disease among

(Concluded on page [illegible].)

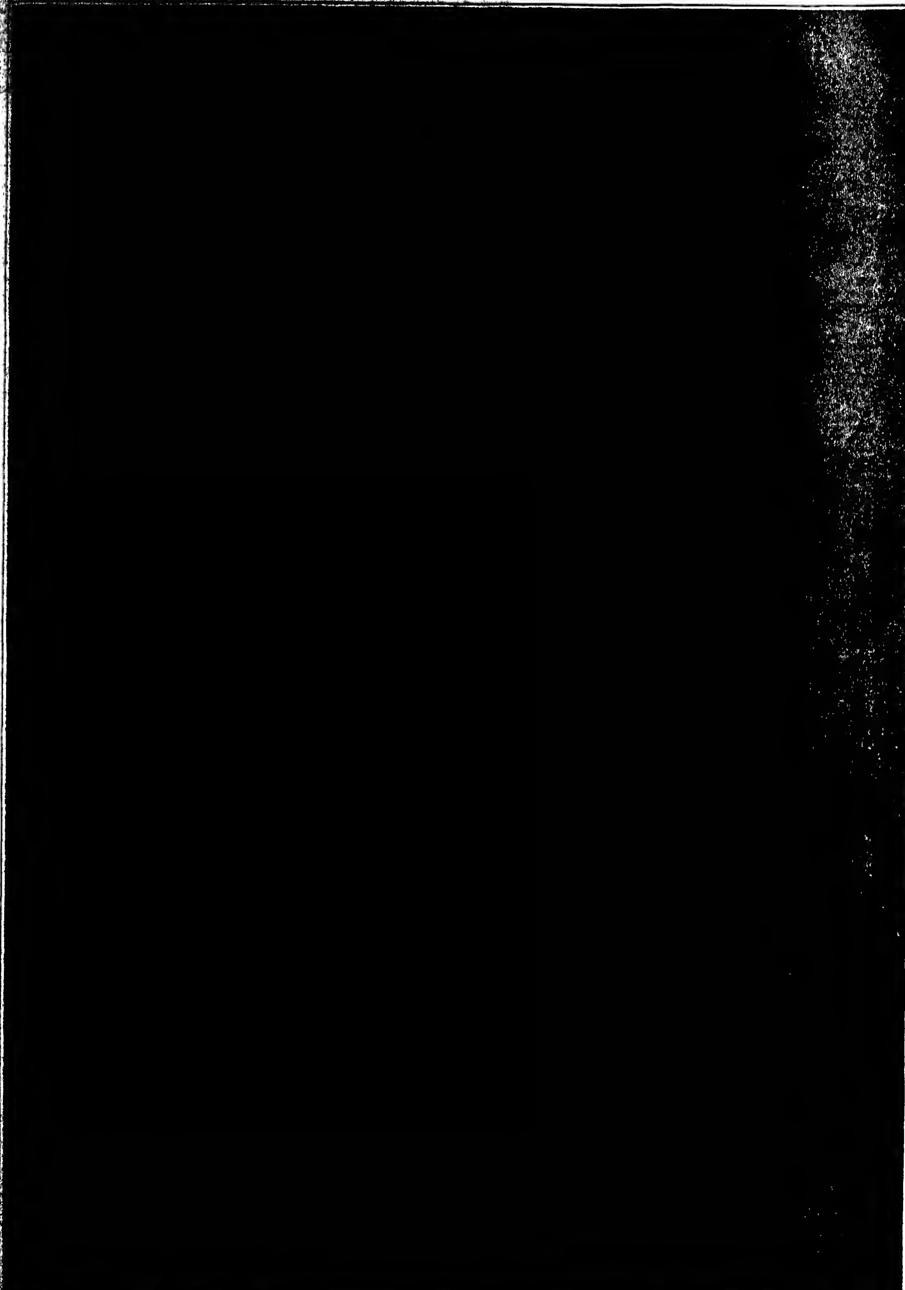
This is a profile of a fly's head.

The large area studded with thousands of facets is one of the fly's compound eyes. A fly sees you not once but hundreds of times in all angular directions. That is why he so readily escapes your downward traveling hand. In addition to the facets he has three simple eyes at the top of his head in the middle, not visible in this picture.



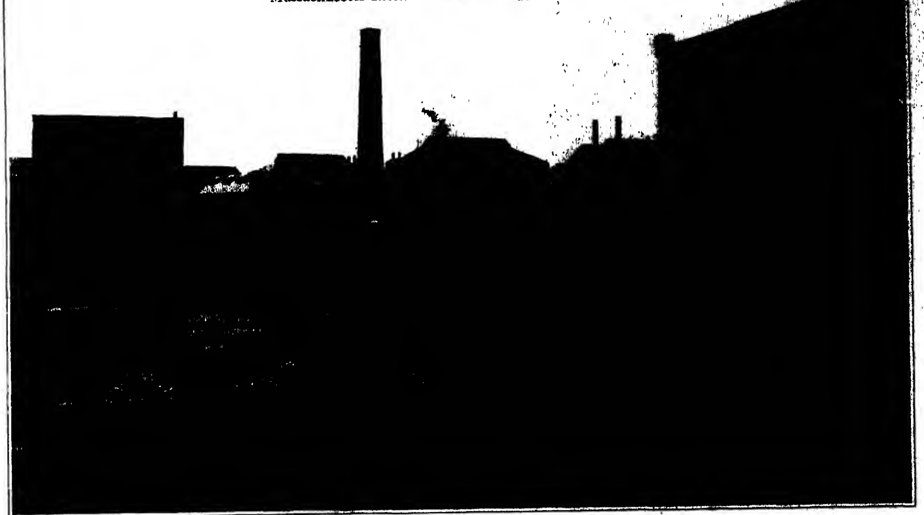
Photograph by N. A. Cobb. By special permission from the National Geographic Magazine, Washington, D. C. Copyright, May, 1910.

Your enemy the fly.

In addition to two claws, each of the six feet is supplied with two light-colored sticky pads. Germs and spores adhere to these pads and are thus carried from place to place with great rapidity, for the fly travels fast and far on its own wings, and on cars, boats and other moving vehicles. The fly cleans its feet carefully whenever they become contaminated, thus removing many of the germs that would otherwise be spread. Unfortunately the cleansing operation is not thorough enough

The Bacterial Purification of Water and Sewage

By Earle B. Phelps, Assistant Professor of Research in Chemical Biology at the Massachusetts Institute of Technology



Filter beds of the Massachusetts Institute of Technology. Three kinds of distribution of sewage to the surface are shown—the small fountain to the left, the spray to the right, and still farther to the right, the fluted cylinder of the Fidian distributor.

[*The author of this article graduated at the Massachusetts Institute of Technology in 1899, proceeding thence to the Lawrence Experiment Station of the Massachusetts Board of Health, where he remained until 1903. In that year he was appointed chemist and bacteriologist of the Massachusetts Institute of Technology in the Sanitary Research Laboratory. His official title at that seat of technical learning is Assistant Professor of Research in Chemical Biology. He was hydrographic aid of the United States Geological Survey (1905-1906) and since 1906 has been hydrographer. His special departments of research have been water and sewage purification. He is an expert in the consideration of remedies for the various evils existing in large cities. In the recent investigation of the pollution of the Hudson and East Rivers at New York, Prof. Phelps was the sanitary authority connected with the work. He devised plans for the immediate improvement of the situation. He gave Newburyport valuable advice on the subject of its clam flats, showed Providence how to improve the condition of its oyster beds and recommended means for the purification of the polluted harbor of New Bedford.*—Editor.]

Water supply and sewage disposal are pre-eminently, although not exclusively, problems of modern community life. Upon the farm or country estate, and in the small villages, nature provides fairly satisfactory solutions of both. Springs or wells, on the one hand, and privies or cesspools, on the other, properly devised and maintained with regard to the elementary rules of health and cleanliness, constitute what may be called the natural solution. With increasing concentration of population the necessities of convenience and public health demand more extensive works. Here recourse is had to what may be called artificial methods, since they call for special scientific study and engineering construction. Nevertheless, as all science is but the orderly and detailed study of nature, so the modern science of water and sewage treatment is but an elaboration and intensive application of the natural processes. To the latter then we must look for the clearest and most basic exposition of the principles underlying the bacterial purification of water and sewage.

The soil has ever been the natural and final repository for the waste products of life. Even the gaseous exhalations of animals are captured finally by plant life and ultimately become part of the carbonaceous surface of the land. The soil has a tremendous and apparently inexhaustible capacity to receive and assimilate such wastes. It has been found that if soil be heated to a killing temperature this wonderful power is lost. In short, the soil, as we know it now, is not the lifeless substance we once thought it to be, but a veritable living world teeming with invisible things, bacteria, molds, and yeasts, as well as with larger animal life, worms and grubs. It is this living soil that devours all manner of waste substances, reducing them ultimately to the simpler mineral ash from which they came. "Dust thou art, to dust returnest" could be spoken of the body no more than of the soul were it not for these great though tiny destroyers.

Let it be said now at the outset that this provision of nature is the starting point of all that follows. As the tea-kettle is to the steam turbine; as the kite and key of Franklin are to radio-telegraphy; so is the living soil to those two greatest achievements of sanitary science, the bacterial purification of water and sewage.

Nor is it wise to separate the two as is so often done. A good water supply is a prime necessity. Sewage disposal is the resulting prime duty. To bring a generous supply of water into a town without making due provision for its satisfactory removal is but a half-way measure that were in many cases better left undone. Such satisfactory removal must always involve the final disposal of the sewage in such a manner that no injury to the health, comfort, or property of the community in question or of any other one shall result.

With these few basic facts set forth, attention may now be directed to the methods by which natural forces have been directed and utilized in water and sewage purification. To further emphasize the importance of the disposal end of the system, and because it best illustrates the principles involved, let it be first discussed.

Sewage Disposal.

The earliest method of disposing of human waste was by burial, and to-day no better method exists. The introduction of water supplies led to the water carriage system of waste removal, by which the problem became one of community interest. Removal is not disposal. It serves but to shift the responsibility from the individual to the central authority; to concentrate the effort from many small natural plants to one large artificial system.

The earliest successful effort to meet this responsibility was by "broad irrigation" or "sewage farming." As early as 1560 the sewage of Bunzlau, Prussia, was thus treated. This method consists simply in allowing the sewage to flow over large areas of cultivated land, where it is absorbed and utilized in a manner strictly analogous to the utilization of manure. At Berlin, the chief city now employing this method, over 43,000 acres of land are utilized.

The comparatively large areas of land necessary, coupled with certain objectionable features of the process, such as offensive odors and the possibility of disseminating disease by means of flies or through the crops, have caused irrigation to be viewed with less favor now than formerly. Even in those places where it is most extensively employed other methods of treatment are gradually being introduced.

From the broad irrigation field to the modern trickling filter progress has been along the line of more intensive action and consequently smaller areas. The Berlin fields provide an acre of land for every hundred people. In the next type of works to be developed the rate of treatment was increased ten-fold. This was the so-called intermittent slow sand filter which may be defined as a specially prepared irrigation field. It is distinguished from the latter in that it is either constructed upon sandy areas by the laying of underground drains, or else built up entirely of sand brought from some outside source. Crops are not as a rule raised upon sand filters, and higher rates of application of sewage are therefore possible. Sand filters of this kind can be made to purify sewage to a drinking water standard.

The use of the term filter is unfortunate. It is hard for anyone who has not especially investigated this matter to appreciate the real biological activity of such a sand bed. In the popular mind the action of straining is always most important, although in reality it amounts to little or nothing. There is, of course, a certain amount of material which will not pass into the sand, matches, paper, fiber, etc., and this has to be raked from the surface occasionally to allow free access of the air. The sewage itself, however, is absorbed and entirely purified within the sand bed, its outflow being a crystal, clear stream. The same natural process which takes place slowly in a manured field is carried out on a more intensive scale in a slow sand filter.

The results of this treatment are well nigh perfect, and no further investigations would be necessary were it not for the fact that in the neighborhood of large cities, land of suitable character and of sufficient extent is seldom available. Especially is this true in certain parts of the country where sand is uncommon. Efforts have been made to overcome both these difficulties by the construction of types of beds utilizing other materials than sand and capable of receiving sewage at much higher rates. The best known of these latter-day processes is the contact bed. This differs from the sand filter chiefly in the fact that crushed stone is employed for a filter medium. In this again we are dealing with biological oxidation of the sewage, an action due to the numerous minute organisms inhabiting the filter. Contact beds need breathing periods during which they

are filled with air, but with these included they are capable of treating sewage at a rate fully ten-fold that of the sand filter. Such a contact bed tends to accumulate material to a certain point, after which it reaches a condition of approximate equilibrium, dissolving and oxidizing the stored material at nearly the same rate at which that material is applied. Curiously enough, the accumulated material within such a bed when removed is found to be quite inoffensive in character and to resemble very closely a rich garden loam.

The latest and most important development in oxidizing filters is represented in the trickling filter. In construction this is similar to the contact bed except that it is deeper; as in the sand filter, the sewage passes continuously through the bed. The greater depth provides sufficient detention of the sewage and the better facilities for the entrance of air into the body of the filter make the oxidizing process more rapid. The trickling filter can treat sewage at rates two or three times those that are possible in the contact filter, so that as a result of 25 years' study the sewage of 25,000 inhabitants can now be disposed of upon one acre of land, whereas in the old irrigation fields one hundred persons was the safe maximum for the same area. This improvement in rate has not been secured without some sacrifice. It is not practicable to secure the perfect results of the sand filter in the rapid processes necessary for large communities. With the increasing rate there has been a decrease in the quality of the purification, especially as regards bacteria. The primary function of purification, oxidation of the organic matter, is performed satisfactorily, so that for the protection of streams and larger bodies of water these methods would suffice. But the effluents or outflows are not clear and attractive and the bacteria have not been satisfactorily removed. From a public health point of view, therefore, much is still desired in sewage purification. Fortunately, the investigator in sanitary science has been equal to the occasion, and means of chemical disinfection have recently been developed which effectively supplement the work of these most efficient oxidizing methods. But chemical disinfection is not strictly a bacterial purification and lies aside from the immediate purpose of this discussion.

The septic tank and its many modern modifications are important in a consideration of sewage purification. These are the offspring of the old-fashioned cesspool, but the modern development is as far removed from the original device as is the trickling filter from the irrigation field. In a septic tank the biological action is very different in character from that which we have considered. Instead of oxidation with an abundant supply of air always present, we find here an anaerobic condition, that is a working without oxygen, and chemical reduction. The natural effect of this action is the rapid solution of solids along with certain other chemical changes, and the liquid thus treated can be discharged upon filter beds of the various types described at even higher rates than would be possible with untreated sewage. Thus, the septic tank and its modern successors, the biolytic tank, the Imhoff tank and all the others, are preparatory treatments only.

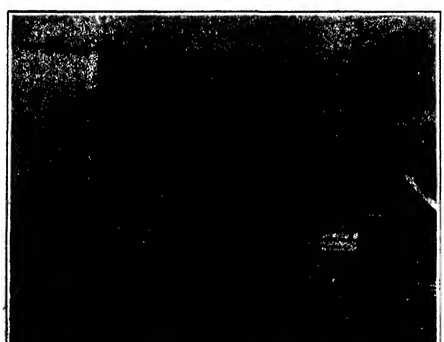
Water Purification.

Just as we have seen how the science of sewage purification employs those very principles by which the soil in nature brings about the ultimate destruction of organic matter, so in the field of water purification we again look to nature for our methods. Despite the obvious fact that the earth is the final repository of all things that have ever lived, both animal and vegetable, and that its surface is literally covered with organic material in the process of return to the mineral world, yet waters issuing from the ground have ever been regarded as the very emblem of purity. Closer investigation shows that this popular belief is well founded. No purer waters are to be found in nature than those which have passed through a considerable body of the earth, save in the single instance of newly fallen rain. One frequently finds pure crystal water issuing from a spring whose obvious source is some nearby, stagnant pool, filled with all manner of animal and vegetable matter, living or in various stages of decomposition. Between the two, therefore, there must be some ample purifying agency. This agency is found to be once more the living earth which has been so frequently referred to. If, now, these natural resources can be developed and intensified so that they may be utilized in artificial structures for the purification of water, the problem of a pure water supply will have been solved. This is exactly what has been accomplished.

Artificial beds of sand only a few feet in depth, carefully prepared with under-drains and properly operated to secure the maximum efficiency, constitute the sand filters upon which so much reliance is now placed in the purification of city water supplies. Within these beds the bacteria find lodgment and increase enormously in numbers. The organic matter contained in the water, constituting its impurity, is seized upon by these small organisms and is transformed by them into harmless mineral residue. Rates of filtration are so rapid that in most cases there is also, incidentally, surface accumulation of debris composed of solid impurities in the water. This straining action is oftentimes regarded as an important factor in the work of these filters. To a certain extent this view is correct, but mere straining action would bring about little purification. The all-important item is the bacterial life within the bed of the filter. When this becomes incapacitated by low temperatures or by other unfavorable conditions, the efficiency of the filter diminishes at once. When conditions are most favorable for biological activity, efficiencies are at their highest. A simple calculation will show that the size of the sand grains is to that of the bacteria about as the size of an apple to that of a bird-shot, and illustrates how futile would be any attempt to strain out bacteria from a polluted water by mere passage through sand. How much more impossible would be the removal by straining of dissolved coloring matter, the dimensions of which are molecular. Yet both bacteria and coloring matter are removed in a well regulated sand filter.

Winter difficulties of a filter.

The sprinkling filter and sand beds at Burlington, New Jersey.



The Fidian distributor, which appears in the head-piece of this article, but revealed more in detail.

The so-called "mechanical filter," developed largely in this country, is a very different mechanism. It operates at a rate about fifty times as great as the permissible sand filter rate and is purely mechanical in its action. For this purpose sand is also employed, although a coarser grade is preferred. Before passing through the sand, the water must first be treated with a suitable coagulant, alum being commonly employed. The alum enters into a mechanical combination with certain natural constituents in the water, gathering together all fine particles of suspended impurities and to a large extent absorbing dissolved impurities, such as color and odor producing substances. After the water has been coagulated in this way, it is allowed to settle, and is passed finally through these rapid coarse sand filters at a high rate. The filters strain out the remaining alum precipitate and the result is clear water quite free from bacteria and other impurities. This process is not truly bacterial purification, but it occupies an important position in American practice. The early objection to the use of alum in the water has practically disappeared. It has been learned that under proper management it is impossible for any alum or any resulting compound to pass the filter and reach the consumer.

These two types of water filtration have quite distinct, although at times overlapping fields of usefulness. The slow sand filter is especially adapted to the purification of sewage polluted waters where the removal of disease-producing bacteria is the object sought. In this field they seem to be distinctly superior to the mechanical filters. The latter are of especial value and even indispensable with waters that are highly colored or that carry clay or mud in suspension.

The most recent development in water purification, and one which has come into very general use within the past few years, is the so-called "hypochlorite treatment." This also is a purely chemical treatment and may be used either by itself or in conjunction with some filtration process. Its sole object is the destruction of disease-producing bacteria. Clear, colorless waters that are only slightly polluted lend themselves admirably to this treatment without filtration. Waters which have undesirable physical characters, color or muddiness are not improved thereby. As an adjunct to mechanical filtration, which, as has been stated, is not alone best able to deal with bacterial pollution, this process is most valuable. Its great economy and its simplicity of operation and excellent efficiency commend it highly. Its value is indicated by the fact that although it has been in use but a few years, it is now employed regularly by most of the large cities of the United States and Canada and by many hundreds of the smaller communities. There is a similar objection raised against this process to that which was raised in the case of alum, but this is bound to be short-lived. The time is fast disappearing when people are going to let weak, sentimental ideas of so-called purity stand in the way of real sanitary and economic progress. Man is frequently able to improve upon nature's work. Pure water is an ideal, but as between purified and unpurified water, even though the former involves the application of a disinfectant, the common sense of the community will not long hesitate. However we may reverence the ideal of purity, we will not take long to choose between disinfectants of well-proven harmlessness on the one hand and typhoid fever germs on the other.

The Problems of a Country Estate.

Thus far we have discussed water and sewage purification for large communities. It is here that the problems are most intense and that their successful solution means most for the welfare of the people.

Sewage and the Farmer

A Problem in the Conservation of Waste

By W. T. Sedgwick, Sc.D., Professor of Biology and Public Health and Director of the Sanitary Research Laboratories and Sewage Equipment Station, Massachusetts Institute of Technology, Boston

[*PROF WILLIAM T SEDGWICK needs no introduction to those conversant with the story of public health education and its movements in the United States. Born at West Hartford, Conn., he graduated from the Sheffield Scientific School, Yale University, in 1877, with the degree, Ph.B., gaining Ph.D. at Johns Hopkins in 1881 and receiving Hon.Sc.D. from his alma mater in 1909 He was instructor of physiological chemistry at the Sheffield School in 1877 to 1879; fellow and assistant biologist at Johns Hopkins in the latter year, coming to the Massachusetts Institute of Technology in 1883. Here, from assistant professor, he has risen to Professor of Biology and Public Health and Director of the Sanitary Research Laboratory He is the man who established at the Institute more than twenty-five years ago the courses in biology, later developed into public health work. So successful have they been that the graduates are directing large sanitary works in many parts of the country Wherever there is an important question of pollution of water supply, or the discussion of conditions inducing infectious disease, he is certain to be consulted He was one of the experts named by Pittsburgh to investigate the typhoid outbreaks in that city. He and his graduates, Winslow and Whipple, constitute the non-medical portion of the New York Typhoid Fever Commission*

In an age when popular enthusiasm is seizing on fragments of scientific truth and magnifying them till they overshadow and obscure the fundamental and important facts, he has opposed the present craze for "swatting the fly," which at best is only warring on a symptom and neglecting the disease, or destroying the danger signal, while yet the danger exists. In these later years Prof. Sedgwick has stood sturdily for conservation. He is opposed to the wholesale destruction of foods because they are merely of inferior quality, and believes that Government supervision should preserve and make safe such products This has brought him into disagreement with some of the Government methods. His present article is in the line of conservation of sewage, which is everywhere turned to waste, but which has in it valuable elements for some of the industrial or agricultural processes. --EDITOR]

The farmer is always seeking for fertilizer for his fields and crops It seems therefore at first sight as if the sewage of our towns and cities ought all to be carefully collected and turned back upon the farms that feed them The farm feeds the city, why should not the city, plus air and sunlight, feed the farm? The idea is very old, yet it seems forever new. Chemistry confirms and enforces it, for nitrogen—that wonderful element, which, in its virgin state, seems so indifferent, so inactive, but in its compounds so full of energy and so much alive—nitrogen flows alike from sea and land, from fisheries and from farms into those living whirlpools which we call cities, there to revolve for a time and finally to be expelled, largely as sewage, in new chemical combinations, lower and less potent in the scale of energy, but still highly favorable as food stuffs for low plants and animals.

Some such reciprocation between city and country there actually is The manure of city horse stables is carefully saved and sent back to the farm. Garbage is not infrequently likewise saved and sent back to piggeries in the suburbs The carbonic acid gas given off by human beings, animals, plants and by the great fires and furnaces of cities mingles with the atmosphere and helps to maintain that mighty reservoir of carbonic acid upon which the green plants of sea and land draw for their raw materials for manufacturing starch and sugar and cellulose—three of the most important elements of human life and industry.

How We Waste Nitrogen.

But water and the nitrogenous wastes of cities are not often thus returned—at least not directly More often they are emptied as sewage into rivers or harbors or the sea, to mingle there with larger bodies of water, which latter material returns to the farmer only after evaporation or distillation into the atmosphere and condensation as rain or snow or hail or fog or dew.

As for the nitrogen of the sewage, this comes back but slowly, if at all, and chiefly in fish, shellfish, seaweed, and other familiar products of the sea, so that there is nowadays a steady and a heavy drain of nitrogen away from the land and into rivers and the sea. The same thing is true of phosphate, and probably to a greater or less extent of the other elementary substances underlying plant and animal life. In short, there is to-day a constant sapping of certain indispensable elements of the food of plants and animals from the land to the sea, and only a limited return of these same elements from sea to land. To some extent this drain upon the resources of the land, and that means of the farmer, goes on even in an uninhabited region, for the ground waters which go to feed the streams, and which in dry times make up a very large part of many streams, always carry more or less nitrogen.

So, too, there escapes, even from a sewerless city, and from a region where the excreta of human beings are carefully collected and used in agriculture, through the ground water which comes from such regions, much nitrogen in the form of nitrates.

But undoubtedly the heaviest loss, the greatest drain, comes with the sewerage of cities and towns, and the quick discharge of solid streams of sewage directly into rivers or the sea without any previous contact with the earth which, like a mighty sponge, would hold the sewage for a time and give opportunity for chemical changes followed by absorption and assimilation by plant life. Under this, the modern, system the draining of nitrogen and phosphates away from the land is rapid and continuous; and it is no wonder that great scientists like Sir William Ramsay are giving to the subjects of "nitrogen exhaustion" and "nitrogen supply" anxious consideration.

The Farmers' Interest in the Sewage Question.

But if the sea is just now the gainer and a kind of nitrogen accumulator, ought not the fish to benefit and multiply exceedingly? And, on the other hand, if all sewage should be used in agriculture and our fishing continue or increase, would not the sea soon be depleted of nitrogen, and the fisheries disappear? This is an interesting question, but one which we need not try to answer here. What we are trying to do is to learn what is the farmer's interest in the sewage question, and that means: How can the farmer best secure the return to his lands of the nitrogen and phosphates which he sends to the city but which the city after using fails to return to him?

The easiest answer is that he should have the liquid wastes of the city at his disposal as he already has the atmospheric wastes and (sometimes) the garbage and the stable manure of cities. In other words, that the sewage streams of cities should be poured, not into rivers or the sea but upon the land, where their precious elements would not be lost or wasted but made over by plants into food for man and beast. This is the simple ideal solution of the sewage-conservation problem and of the prospective difficulties of the farmer.

The Effect on Fish of Withholding Sewage.

But it should be noted in passing, that this plan, perfectly carried out, would very likely seriously deplete or at least damage our fisheries, since fish life is rich in nitrogen and the amount of nitrogen in the sea, though immense, is not unlimited. Moreover, the theoretical way out is beset with many practical difficulties. The worst of these is the seasonal and climatic difficulty. Sewage is a constant, daily product of urban life, and must be disposed of daily and even hourly, rain or shine, in summer and winter, in wet weather as well as dry. But the needs of plant life are not thus constant or perennial, but highly variable, according to season, climate, temperature, rainfall and many other conditions. There is thus this difficulty: If sewage is to be disposed of satisfactorily to the community which has it to get rid of, it must be taken away by river, sea or farmer completely and uninterruptedly; by night and day, summer and winter, rain or shine.

This requirement is easily met by rivers or lakes or the sea, but not by the farmer, at least in regions of marked seasonal variation and considerable rainfall, for at times his crops, simply cannot and will not absorb any additional liquid, however nutritious. Hence the sewage at such times must flow off unpurified and liable to create a nuisance, while the crops suffer from excess of water. In the arid or the semi-arid regions the farmer may perhaps at all times and all seasons welcome the arrival of the sewage stream upon his land, for irrigation with sewage ought to be the best and most successful form of irrigation in such regions.

It is certainly a significant fact that very few, if any, successful sewage farms exist to-day in the eastern part of the United States. The subject of sewage disposal has now been agitated in America for about twenty years and during these years the problems of extended and improved agriculture have been studied as never before in this country by the U. S. Department of Agriculture and by the Agricultural Colleges and Experiment Stations of the several States; and yet it remains true that there is not one important example of extensive and successful sewage farming in the populous and urban Eastern United States. On the contrary, New York, Boston, Philadelphia, Baltimore, Washington, and many lesser seaboard cities pour their sewage into the sea, while Chicago, Cleveland, Milwaukee, St. Louis, St. Paul, Minneapolis, Cincinnati, Louisville, and many minor cities of the interior empty their sewage into rivers or lakes connected with the sea, so that the farmers nowhere recover from these cities the elements which they contribute to them.

The reason for this common practice is plain. It is easier and cheaper to secure quick, convenient and constant disposal of the huge volumes of sewage which our cities must get rid of, by the means actually adopted than by disposal upon land. And yet, if the sewage of Boston could be carried to Cape Cod, or that of New York to the sands of Long Island, Philadelphia's to the Pine Barrens of New Jersey, or that of Baltimore to the sometimes poor and thirsty soil of the Eastern Shore of Maryland, then might these comparatively desert places be made to blossom like the rose. But even so the fish of the sea would suffer, the gardens of the ocean being robbed to feed those of the land. Perhaps we have here only one phase of a world-old dilemma: the land rising solid from the sea only to be dissolved in rain and carried back to it in aqueous solution; the elements then picked out from the solution by plant and animal life, thoroughly deposited in shells or skeletons, and at death added together to make once more the solid earth.

It may be that if we do not use our sewage upon the land we shall by and by be driven to seek our food more and more within the sea. The Japanese and the Chinese eat not only fish but seaweeds, and it would be strange indeed if Americans likewise should give up the land vegetables of to-day for the sea weeds of to-morrow.

Objections to the Farm Use of Sewage.

From the sanitary point of view the utilization of sewage in farming is open to some serious objections. In the first place, the mere fact that sewage is brought to the farm at all, means that disease germs and parasites may come with it to places and persons previously free from access to a contact with these undesirables. In the second place, owing to the difficulty of escaping contact with it, farm hands, and through them their families, will be especially exposed to personal infection and in some cases to air pollution also. In the third place, certain products of the farm, and especially vegetables such as celery, radishes, turnips, beets and beet tops, spinach, water cress, lettuce, potatoes and onions; and certain berries or other things grown upon or near the earth, such as strawberries and peanuts, which are either eaten unwashed or "handled" preparatory to cooking; if they are irrigated with sewage or are grown on soils recently flooded with sewage, may become soiled with particles of excrement and infected with dangerous microbes or other parasites.

It must be confessed, however, that the experience of Berlin, the capital of the German empire, where the sewage of upward of two millions of people is disposed of upon sewage farms, seems to show that this danger is more theoretical than actual; for the death rate of Berlin from typhoid fever is one of the lowest among the great cities of the world, and the experience of Berlin in this respect is confirmed by that of many smaller cities in England and elsewhere. If it be asked why it is that Berlin, almost alone of all the greater cities of the world, has adopted sewage farming as its means of sewage disposal, the answer is that owing to its inland situation Berlin was compelled to devise some other means than sea disposal, and having only a small stream in its vicinity, was obliged to resort to some form of disposal upon land, i. e., either to intermittent filtration or to broad irrigation (sewage farming). The former is land disposal without reference to the giving of crops, the latter land disposal combined with agriculture or horticulture.

The conclusion of the whole matter is that, except in the more arid portions of the United States, the utilization of sewage in farming does not seem likely to increase at present. Consequently, we may have to look in the future for our supplies of food more to the sea and less to the land.

Curiosities of Science and Invention

READERS are invited to contribute to this department photographs of novel and curious objects, unique occurrences, and ingenious contrivances. Such as are available will be paid for promptly.

The Licensed Sand Sculptor

THE sand sculptor, familiar to visitors to the sea shore, has advanced from a small beginning and a somewhat checkered career to the dignity of a regularly recognized artist. At first the efforts of this picture maker were crude in the extreme. Fashioned from real sand the figures he produced were scarcely worthy of serious notice, either as art productions or as a bid for the coins of the beneficent. It was almost impossible to work with sand alone, and as the productions were as unsubstantial as the snow figures of the winter season, no one was interested in the "artist's" work to the extent of more than a glance in passing on the boardwalk at one of the seaside resorts.

But in this country no one is satisfied for long with crudities. While sand artists abroad continued to work in sand alone, the American "sculptor" experimented with various materials until he had found something that would pass as sand but which was almost as substantial as hardened clay. As soon as the improvements began to be evident and the public began to take serious notice of the sand artist and his work it became a profitable business and the sands along the boardwalk began to swarm with "artists." Many were quite ignorant of art, but contrived to fashion a few figures that a good-natured public recognized as well intended, and rewarded with small coins. Some were genuine artists seeking in this way to pay for a summer vacation, or students trying to earn enough in the summer to weather the financial storms of the winter. These of course were annoyed by the ridicule brought on the business by the unskilled ones and encounters took place between rivals that at last compelled the authorities to take notice of the presence of the sand artist colony and take steps to regulate the business in some way.

Atlantic City was the first sea shore resort to insist on a license being first obtained before any one could stake out a claim on the sands and start business as a sand sculptor. There was appointed a committee to examine the work of the various artists and pass on its merits. The decree went forth that all work that could not pass muster with the committee as possessing some sort of art merit should be demolished and the artist driven from the beach. Some of the workers had been unwise enough to stoop to vulgarity in their creations and this hastened the work of the committee. The long line of sand sculpture exhibits that stretched along the front of the boardwalk was inspected closely and the committeemen retired to compare notes and report. Next day a band of large-footed policemen marched down the line and whenever they reached a sand sculptor's exhibit that had come under the ban they proceeded to stamp it to pieces, with a warning to the "artist" to come there no more. As a result of this proceeding the exhibits that will be seen this summer are only those that are really attractive and have some claim to being artistic.

The figures are made of sand and cement mixed, to give the finished work the hardness of mortar. One of the best sand artists, the leader of the colony at Atlantic City, originated the exhibit of classic figures shown in one of the photographs. He was the first to construct his sand display on a slanting base so that the exhibit faced the board walk at an angle suitable for observation and he also gave the figures a coat of white paint which brought them out in bold relief against the dark sand. It was not long before others imitated the classic artist and even improved upon his idea. Subjects were selected that lent themselves to original coloring and with fine disregard for historical correctness the sculptors adorned George Washington, standing in the boat of sand in the act of crossing the Delaware, with a bright red coat and provided his sailors with blue shirts and his attendants with sartorial accessories of any hue that harmonized with the general color scheme.

An 80,000 candle power searchlight for a transatlantic liner.

A clever bit of work done in sand and cement.

General view of the classic figure exhibit.

"Empty" gasoline barrel exploded by the sun's heat.

First Searchlight for Transatlantic Liners

THE most powerful searchlight ever carried on a merchant ship was a conspicuous feature of the "Kaiserin Auguste Victoria," which arrived in New York recently. The great light, which is the largest type ever constructed, is designed for the steamship "Imperator." It is being carried across the Atlantic to be thoroughly tested at sea and on entering harbors. It throws a beam of light of 80,000 candle power. On approaching port, the searchlight was turned on the Scotland Lightship, rendering the name of the ship clearly visible at a distance of several miles. The great light is effective for seven miles at sea, and when thrown upon the clouds is clearly visible for a distance of thirty miles.

The searchlight reached the vessel only three hours before her sailing and was carried on the forward deck. It will be installed on the lookout, high up on the mainmast, where it can be swung quickly to any angle. The searchlight is of the type used heretofore only on the largest dreadnought battleships. The lens is 42 inches in diameter. It is operated by a current of 13,000 watts on a 110-volt circuit. In actual tests at sea, the ray has pierced fogs and distinguished distant objects at every point of the horizon.

Precautions With Empty Gasoline Barrels

THAT gasoline is dangerous is pretty generally understood, though the death toll from careless handling is heavy. Usually familiarity with any dangerous thing breeds contempt, but even down in the "oil country" gasoline is treated with a respect that is greater than that given to nitroglycerine.

Many persons have always had the wrong idea regarding the dangers from gasoline. They have taken the greatest precautions with the full barrels and have given scant attention to the partially filled and empty ones, in fact, very few dealers and users have ever given any thought to the care of empty gasoline barrels. That this is wrong is shown by the accompanying photo of an exploded "empty" gasoline barrel. This barrel "went up" while standing in the hot sun on the platform of the freight station. It is a 50-gallon barrel made of heavy iron. The heads are of a single sheet, slightly crowned and set on a projection rolled on the inside of the cylindrical barrel sheet. A solid welded ring is placed against and around the head and the end of the sheet is rolled over the ring and tightly crimped. In the exploded barrel the head was bulged like a grocer's scoop, the ring torn apart and the crimp of the barrel sheet pulled out straight. This explosion made a very loud report and the pieces were blown to a great distance. Fortunately, no one was injured, though some damage was done to other equipment about the barrel. By "empty" gasoline barrels is meant those that have been unloaded by dealers or garages, both public and private. They are the barrels rolled out to be returned to the refineries for refilling. These barrels are a source of danger and should receive greater care. The cause of the explosions of these barrels is the excessive pressure of the gasoline vapor generated when standing in the hot sun. A little oil is liable to be left in them and if the vent plugs are screwed in tightly there is danger of an explosion. Drain the barrels thoroughly and have the vents opened; also store the barrels in a cool or shady place.

Inventions New and Interesting

Stagmatypy: A New Half-Tone Printing Process

If a solution of gelatine is cautiously mixed with one of gum arabic the two do not coalesce into a single homogeneous solution, but form an emulsion composed of minute drops of gum suspended in the solution of gelatine. If a glass plate is coated with this emulsion an irregular vibratory movement of the gum globules, of the character of the Brownian molecular motion, may be detected with the naked eye, while observation with a microscope shows that the minute globules gradually agglomerate into larger, though still very small spheres, which finally come to rest at approximately equal distances from one another. The configuration can be fixed by carefully drying the plate.

A plate of copper or zinc coated in this manner with a gum-gelatine emulsion which has been made sensitive to light by the addition of potassium bichromate, forms the starting point in a new and remarkable half-tone printing process which Dr. Hans Strecker has devised, and named stagmatypy, from the Greek word *stagma*, a point.

In all methods of reproducing, by the printing press, photographs or other pictures having a continuous gradation of light and shade, the various tints, technically called "half tones," are represented by lines or dots separated by white spaces. All of these lines or dots are necessarily of the same color—that of the ink used in printing—but they vary in width according to the depth of tint, so that every gradation of the original picture, from black to white, is represented by the proportion of black lines or dots to white spaces in the corresponding part of the reproduction, as in a highly elaborated pen-and-ink drawing. This principle applies to all varieties of printing plates, including relief plates in which the raised portions alone take ink from the roller, as in wood-cut printing, etched plates in which the ink is wiped off the general surface but not from the depressions, and lithographic plates, which take the oily ink only at parts prepared for printing by previous applications of such ink.

The disintegration of the half-tones into separate lines or dots is usually accomplished by photographing the original picture through a fine grating of parallel lines or network of intersecting lines, photographed on glass. The result is a mechanical, lifeless print which often fails signally to reproduce the individuality of the original. The actual pattern of the grating, fortunately, is apt to escape the notice of the superficial observer, but it appears conspicuously under a magnifying lens and is often apparent to the naked eye. A person who has seen it in one picture is tempted to look for it and find it in others, and then his eye involuntarily follows the straight lines of dots, and the artistic effect is spoiled.

Several processes have been devised for making the "grain" of the picture less regular, but none of them have achieved complete and lasting success. In some of these processes the picture is photographed through a stippled or dotted screen, while in others no screen or grating is employed, but the "grain" of the half-tone print is produced by particles of asphalt applied to the metal printing plate in the form of dust, and then fused, before the sensitive film is applied. In the heliogravure process, for example, the polished copper plate is first dusted with asphalt in a special apparatus, and a second operation is required to melt the dust and attach it to the plate. A photographic copy of the picture is made on paper coated with bichromated gelatine and the undeveloped print is applied, face downward, to the asphalted copper plate. The paper is then washed off, and the gelatine film, which remains attached to the plate, is developed into a picture in relief by the action of hot water. This process, which is common to all half-tone printing methods, is based on the property of bichromated gelatine to swell in hot water to a degree inversely proportional to its exposure to light. After all of these operations the plate is etched by immersion in a bath of ferric chloride.

Even the ordinary half-tone process is tedious and laborious in comparison with stagmatypy, and the glass gratings employed are costly and fragile.

This half-tone was printed from a Stagmatype plate

The new stagmatype process is remarkably simple. The granulation required to reproduce the half-tones is effected automatically by the agglomeration and precipitation of the gum globules when the bichromated gum-gelatine emulsion is poured on the metal plate, forming a grain of approximately but not entirely regular pattern which, when dried, resists the action of the etching fluid very well. The plate is then exposed under an ordinary negative and immediately etched without having undergone the separate operation of development followed by drying and varnishing, which the ordinary half-tone processes require. The four distinct operations employed in heliogravure, namely, the formation of the grain, the coating of the plate with the sensitized or exposed film, development and etching, are replaced by two operations in stagmatypy. The grain is formed automatically during the coating of the plate, and development and etching are effected simultaneously by immersing the plate in a solution of ferric chloride, the water of which produces the development while the iron salt, diffusing through the film, etches the metal in exact correspondence with the progress of development.

This remarkable simplicity makes stagmatypy much cheaper, as well as more expeditious, than heliogravure or the ordinary grating method, both of which it may replace with advantage. The only conceivable additional amplification would be to make the original photograph directly on the printing plate, and even this may prove to be practicable.

Another example of Printing by Stagmatypy

Another advantage of stagmatypy over the ordinary half-tone process is the greater richness of detail obtained in the print. It is obvious that a photograph made through a grating or net cannot reproduce every point of the original. A continuous black line, for example, is necessarily represented by a broken line. In stagmatypy, on the contrary, the unaltered negative is laid directly on the printing plate, the grain of which is formed automatically according to the character of the picture, so that the reproduction of a black line is as continuous as the original. For the same reason, the stagmatype reproduction shows a great superiority in contrast and depth of shadows—qualities in which the ordinary half-tone print is sadly deficient.

In order to obtain fairly satisfactory results by the usual half-tone methods it is necessary to use very finely ruled screens and the best grade of printing paper, and to employ great care and skill in all of the operations. This is not commercially practicable for ordinary work, in which coarser screens are employed, with inferior results. In this respect, also, stagmatypy presents an advantage, for a coarseness of grain that would be intolerable in an ordinary process print is barely perceptible in a stagmatype print, where the grain is not arranged in straight lines and set figures. On the other hand, the automatic stagmatype process can be made to furnish a much finer grain than can be obtained from ruled screens. Stagmatypy, therefore, may be applied to all grades of paper and subject, from the finest art reproductions to newspaper illustrations.

The new process is particularly advantageous in color printing, because it cannot produce the *moiré* effect which is often caused by inaccurate adjustment of the regular patterns of the several colors in the ordinary process. In stagmatypy the colors are automatically blended, and their proportions can be regulated in a novel manner by varying the size of grain for the different tints.

The most important application of stagmatypy appears to be to lithography, both monochrome and polychrome. By printing the stone with a stagmatype plate etched in intaglio a wonderful softness of effects is produced, as only the fine interstices of the granulation are impressed on the stone. Another interesting application is to the direct reproduction of drawings in pencil, charcoal, crayon or India ink without the intervention of the camera. The drawing, executed on a sheet of gelatine or similar transparent material, is laid on the sensitized stagmatype plate in a photographic printing frame, and the plate, after exposure, is simultaneously developed and etched, in the manner described above. In lithographic copies made in this way the character of the medium, pencil, crayon, etc., is reproduced with wonderful fidelity.

For etching the stagmatype plates Dr. Strecker has devised an electrolytic method which greatly facilitates the operation. The plate, suspended in the ferric chloride solution, forms the anode. An amperemeter, included in the circuit, indicates the moment at which the action begins and the rapidity with which it progresses. Hence, the etcher is not compelled, as he is in the useful chemical method, to follow the progress of the action on the plate itself with the greatest care, in order to replace the strong etching bath by a weaker one at the right moment. He can, therefore, conduct the etching of a number of plates at the same time. The electrolytic etching process can be applied to zinc, brass or steel, as well as to copper.

Stagmatype plates retain their sensitiveness

[illegible] copper plates [illegible] zinc plates for more [illegible]. Hence they are likely to become articles of commerce, like ordinary dry plates.

The Trade-mark as a Business Asset

By W. E. Woodward—I

[*THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer; that it is a symbol of good will, a tangible asset with a determinable money value; that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.*

The following is the first of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analysis of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

If you should find in your Santa Claus stocking, next Christmas, a gift of the exclusive right to use the word "Royal" as a name for baking powder, you would be $8,000,000 richer than you were the day before. It is said, on good authority, that the Royal Baking Powder Company considers its trade-mark worth just $1,600,000 a letter. This is, perhaps, the most valuable trade-mark in existence, though it is rivaled in value by "Kodak," "Uneeda," "Ivory" (as applied to soap), "Coca-Cola," the name "Gillette," used in connection with safety razors, and a half-dozen others. Each of these trade-marks has become a national institution. To displace them in the public mind would require competition of unheard of magnitude and energy. The name "Coca-Cola" is worth at least $5,000,000; the Gorham silverware mark, $2,000,000, at a fair estimate; the trade-marks of the National Biscuit Company, all of which touch the highest standard of distinctiveness, must be the largest asset of that concern; and the name "Kodak"—where would the Eastman Company's business go to if it should hand over the trade-mark "Kodak" to some other concern, and go on making the same goods under the name of Smith's Hand Cameras? When the American Tobacco Company was recently dissolved into separate concerns, under the order of the Supreme Court, the trade-marks of the combination were estimated to have a value of $45,000,000, out of total assets of $227,000,000.

The aggregate total value of well-known American trade-marks must be in the hundreds of millions of dollars. But any estimate of the value of a trade-mark, apart from the business to which it applies, is necessarily a mere guess, for a trade-mark is a species of commercial property that cannot be sold by itself. It is inseparably attached to the business from which it emanates, and cannot be transferred without a transfer of the business. There are cases where a concern's trade-mark has become so valuable, through long years of popularity and profit-making, that it entirely overshadows all other assets of the business—in short, the business could not exist without it. A trade-mark is a symbol of good-will—using "good-will" in the same sense that the bookkeeper uses it. It stands for built-up reputation; it is the link that connects the ultimate consumer with the manufacturer. It preserves the identity of merchandise, and, in carrying out this function, it is a device of inestimable value to the commercial world.

Sometimes a complex chain of events is best explained by a simple illustration. With this idea in mind, let us put ourselves in the place of a woman who wants a cake of Ivory soap. She lives in a desert town in Arizona. She cannot go half across the continent to Cincinnati to buy a five-cent cake of soap from the makers. In fact, it is a safe bet that she never heard of the makers, but she knows that she wants Ivory soap. So she sends her little girl down to the "general" store, and this lisping messenger asks for "Ivory" soap—not just plain "soap"—and brings the familiar package with the name on it back to her mother. If the storekeeper sends some other kind of soap the owner of the nickel knows instantly that she did not get what she wanted.

By means of the trade-mark "Ivory" the manufacturers in Cincinnati deal with this buyer in Arizona as surely and as expeditiously as if she lived across the street from their factory. Trace this transaction backward, and you will find its trail running unerringly through the retailer, the wholesaler, and the jobber to the manufacturer—and at every stage of its journey the product kept its personality. It left Cincinnati as Ivory soap, and as Ivory soap it was put into the consumer's hands.

Selling by trade-mark is one of the miracles of modern merchandising. Its development to a state of high efficiency has taken place during the last hundred years.

The early decades of the nineteenth century witnessed the rise of three great forces which were destined to accomplish, in a short time, the most profound changes in manufacturing and selling methods. These forces were:

1. The application of steam power to manufacturing in a large and economical way.

2. The development of cheap and quick transportation.

3. The invention of means for the rapid dissemination of intelligence.

Factories employing thousands of hands—great industrial monuments to cheap power—had inevitably to find distant markets for their products. No longer could the manufacturer sit at home and await the buyer. His product was too large and its burden was too heavy to carry on a hap-hazard sales plan. Consequently, the selling departments of all enterprises grew tremendously in importance. Customers were sought across the breadth of a continent. Many a manufacturer's sales area grew, in the span of a generation, from a few hundred square miles to a region that included every degree of climate from the arctic to the torrid. To accomplish this result, efficient selling methods and economical and fast transportation were required. As a natural consequence of these conditions trade-marks grew in importance. Manufacturers without trade-marks found that they had no hold on their trade. The consuming public did not know them or their products by name, and they were at the mercy of the jobber, the wholesaler, and the retailer. They were supported by a chain of circumstances, of which every link was weak.

On the other hand, manufacturers whose trade-marks were firmly fixed in the public mind by reputation, began to see that they were, to a large degree, independent of the merchandising chain. The ultimate consumer knew their trade-marked products, and asked for them by name. Thus, by a process of natural evolution, the trade-mark developed in importance from a workman's tool mark to a symbol of good will—a business asset in a tangible form.

It is an axiom of legal philosophy that when a thing becomes valuable or desirable, legislation concerning its regulation and protection springs into being. Consequently one looks for, and finds, the beginning of specific legislation on the subject of trade-marks around the end of the first quarter of the nineteenth century.

Before the first trade-mark legislation, cases of infringement fell under the common law, and were decided in courts of equity.

H. D. Nims, a well-informed writer on trade-marks, says in his "Law of Trade-marks and Unfair Trade":

> It is rarely that one life sees the genesis and maturity of law, yet it has almost seen them of trade-mark law. In the eighteenth century there were a few scattered decisions which turned almost wholly on the question of fraud. With the rise and growth of machine-made merchandise in the earlier part of the last century, the matter of private marks of merchants to distinguish wares going out into the public markets of the world assumed importance and cases multiplied. Trade-mark law is one of the results of machinery. It is safe to say that the great mass of trade-mark and unfair-trade law is the development of the last forty years.

A structure, of which the foundation has been so recently laid, must necessarily be still unsettled. The rulings of both the Patent Office and the courts are, in many cases, contrary to precedent. In some instances, courts in different parts of the country have handed down contradictory decisions bearing on the same question. But, despite these drawbacks, a body of trade-mark law is being slowly formed, and it is only a question of time before our feet will be on firm ground.

Trade-mark cases should be entrusted to lawyers who have specialized in this branch of the law. The legal status of this subject is changing so swiftly that an ordinary lawyer, absorbed in general practice, cannot keep track of it.

A trade-mark has been defined as "any sign, mark, symbol, word or words which indicate the origin or ownership of an article as distinguished from its quality, and which others have not the equal right to employ for the same purpose. In its strictest sense, it is applicable only to a vendible article of merchandise to which it is affixed." (Ball v. Broadway Bazaar, Court of Appeals, N. Y., 87 N. E. 674.)

We give this definition because it expresses in the fewest possible number of words the function and limitations of trade-marks. Also, because there is in the minds of many business men, a confused notion of the difference between a trade-mark and a trade-name. By referring to the definition it will be noted that a trade-mark is "applicable *only to a vendible article of merchandise to which it is affixed*."

On the other hand, a trade-name applies to a business as a whole, although this business may be engaged in the sale of not one vendible article only, but a thousand. For instance, "Wanamaker's" is a trade-name and "Kodak" is a trade-mark.

A trade-mark has no value except that created by the quality, sale, popularity and profit in the article to which it is affixed. No matter how distinctive or attractive a mark may be, it is worth but little if it is used in connection with an inferior article or with an article sold without profit.

But a distinctive and suggestive trade-mark is of immense help in advertising and selling. Consider, for example, the trade-mark of Old Dutch Cleanser. It is full of *human interest, motion, life,* and *suggestion.* It brings up in the mind the mental picture of dirt fleeing from an energetic Dutch scouring woman. That this mark has been a powerful aid to sales is obvious. Suppose Old Dutch Cleanser had been called Climax Cleaning Powder? Can you imagine anybody getting together anything more than the most languid interest in anything with a name so dull? It reminds one of hard and sordid toil.

Notes for Inventors

Wanted: A Domestic Dough Kneader.—Boys down South can remember how their mothers made beat biscuits, known as "Maryland Biscuits." By means of a fluted roller of hard wood journaled in upwardly projecting cleats at the sides of a bread board, the material was mixed. The roller had a hand crank. The board was large and clumsy and it was quite a job to hold the board and turn the roller in the stiff dough. Why does not some inventor devise a small compact dough worker adapted for domestic use, having means for securing it rigidly to a suitable support and so geared as to render its hand operation easy for a woman or child?

To Protect the Aviator.—Francois Rillean of Los Angeles, Cal., in patent No. 1,027,346, provided an inflated double-walled body in the form of a frame having an opening or cavity to receive the aviator, a double-walled roof forming a head protector and the floor of the cavity forming a seat for the aviator.

Opening a Sash Lock from Outside.—If you have ever forgotten your door key and found all windows locked, you will appreciate the importance of this suggestion: Some one should devise a sash lock which can be opened from outside by any person party to the secret. There might be some form of combination or some secretly disposed tripping device, by which the lock could be released whenever the necessity arose. If the improvement lock should be slightly more expensive than the commercial lock, it would only be necessary to apply it to one sash, that on the window most convenient to enter, and it would often be found useful when the door key had been left in the house.

A Trough-shaped Aeroplane.—Joseph A. Williams of Cleveland, O., has patented, No. 1,027,954, an airship in which the plane is in the shape of an open-topped wedge-shaped trough which increases in depth and width from its front toward its rear end, is open at its ends and has a suitably driven propeller at the rear wide end of the trough.

Made Money by Invention.—An attorney tells of a client who went to Washington a little over a year ago to secure a patent. Recently when in Washington, he told of having made sixty-five thousand dollars the past year by the manufacture and sale of the invention. He produced an article that went into almost general use in a very active, prosperous industry and his problem became simply one of supplying a persistent demand. To find an active industry and supply a revolutionary improvement is a royal road to fortune.

Death of Major Janney.—Major Eli H. Janney, the well-known inventor of the automatic car coupler, recently died at his home in Alexandria, Va. The Major was a native of Loudon County, Va., and entering the Confederate army became a staff officer of Gen. Robert E. Lee. Shortly after the war, while engaged in business in Alexandria, he conceived the idea of the automatic coupler which for so long bore his name, "Janney coupler," and was a representative of the type which has come to be known as the M. C. B. or "Master Car Builders" coupler. He soon demonstrated the practicable character of the invention by its actual use on a Virginia railroad, and the importance of his invention is acknowledged throughout the entire railroad world. Although more than eighty years old at the time of his death, he is said to have been engaged up to about two years ago, when stricken with his last illness, in experimenting with improvements upon his original invention.

Safety Appliance for Airships.—Louis W. Stolp of Washington, D. C., has secured a patent, No. 1,029,475, for a safety appliance in which there is a movable element which holds the operator's seat in place upon the framework of the machine. A parachute is connected with the operator's seat and has automatic means to open its umbrella portion. Means are provided for releasing the operator's seat by hand from its connection with the framework of the machine and means are also provided which automatically release the opening means for the umbrella portion when the seat is released. By this construction, in case of accident, the operator can relea[illegible] seat from the machine and will at the [illegible]ime release the umbrella portion of [illegible]rachute, so it may operate to con[illegible] his descent.

INQUIRY COLUMN

READ THIS COLUMN CAREFULLY.—You will find inquiries for certain classes of articles numbered in consecutive order If you manufacture these goods write us at once and we will send you the name and address of the party desiring the information There is no charge for this service **In every case it is necessary to give the number of the inquiry.** Where manufacturers do not respond promptly the inquiry may be repeated MUNN & CO., Inc.

Inquiry No. 9240 Wanted, addresses of owners of limestone beds running not less than 98 per cent, and near a railway

Inquiry No. 9241. Wanted addresses of owners of deposits of molders' sand suitable for heavy castings

Inquiry No. 9242.—Wanted, addresses of makers of bag valves.

Inquiry No. 9243.—Wanted address of maker of Rover's monogram embossers

Inquiry No. 9244. Wanted, address of manufacturers making rollers, scrapers, and driers suitable for making soap leaves

Inquiry No. 9246. Wanted, addresses of parties having raw materials or minerals containing potash in any form

Inquiry No. 9247.—Wanted, to buy a Parmelee aerated water

Inquiry No. 9254.—Wanted the name and address of manufacturers of lead pencils and pen holders, such as are used for printing advertisements on

Inquiry No. 9255.—Wanted to buy a patent roller, a ball bearing axle which could be purchased on a royalty basis, it must be cheap and fully proved.

Inquiry No. 9256 Wanted addresses of parties having Pitchblende deposits if able to ship ore

Inquiry No. 9257. Wanted addresses of firms selling second-hand water turbines

Inquiry No. 9258.—Wanted addresses of parties having gem materials to offer in any part of the world

Inquiry No. 9259.—Wanted to buy a machine for removing the coating of a filbert

Inquiry No. 9260.—Want addresses of parties able to ship corundum garnet flint, emery or any material suitable as an abrasive

Inquiry No. 9261.—Wanted, a manufacturer to make card games

Inquiry No. 9262 Wanted, to buy a glass which is a conductor of electricity and the address of the makers of the same

Inquiry No. 9263.—Wanted name and address of manufacturer of pantaloon stretchers with clamps which is capable of being folded up

Inquiry No. 9264.—Wanted the name and address of manufacturers of Date Pitting Machines.

Inquiry No. 9265.—Wanted, names and addresses of manufacturers of machinery for making picket fences

Inquiry No. 9266. Wanted, to buy machinary for fastening wire cloth to wooden frames with coppered tacks

Inquiry No. 9267.—Wanted addresses of manufacturers of metal specialties in connection with plate or window glass.

Inquiry No. 9273.—Wanted to buy a globe for a parlor fountain, working on the Heron system.

Inquiry No. 9274.—Wanted, the name of a manufacturer of a machine to make cushion covers for fruit crates

Inquiry No. 9275. Wanted, name and address of manufacturer of stock patterns of platen job printing presses

Inquiry No. 9276. Wanted a household convenience and necessity which can be retailed at a profit at a price of from $1.00 to $2.00

Inquiry No. 9277. Wanted. A machine for packing dry batteries.

Inquiry No. 9278. Wanted. A machine for separating crab meat from the shell.

Inquiry No. 9279. Wanted. A machine for shredding asbestos board.

Inquiry No. 9281.—Wanted to buy machinery for bleaching walnuts and ivory nuts.

RECENTLY PATENTED INVENTIONS

These columns are open to all patentees. The notices are inserted by special arrangement with the inventors. Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN

Pertaining to Apparel.

BELT.—T HERSHKOWITZ, 944 Union Ave., Bronx, N Y. This invention provides a resilient belt for trousers mounted upon the waistband thereof to maintain an approximately constant pressure on the person of the wearer while expanding to accommodate the movement of the person; provides resilient means for said belt to increase the period of service of the belt; and provides guide members for the belt, said members being attached to the trousers.

Pertaining to Aviation.

AEROPLANE.—D. R. DAVIS, Franklin and Willard Sts., Hollywood, Los Angeles, Cal. This invention is applicable to various types of aeroplanes, but particularly applicable to that type in which the balancing is effected by a relative movement of the parts of the main supporting plane Automatic means provide to keep the main body in its proper position when cross or vertically-directed currents of air are encountered.

Electrical Devices.

TELEGRAPHING INSTRUMENT.—C. E. FERGUSON, 841 St Nicholas Ave., Manhattan, N Y. This invention produces an instrument attachable to a typewriting machine for use in conjunction therewith whereby the telegraphing instrument is operated in harmony with the typewriting machine; produces an instrument which may be adapted as an attachment to typewriting machines of usual construction; and provides an attachment wherein the telegraphing circuit is closed when the use of the instrument is discontinued.

Of Interest to Farmers.

PLANTER.—R ALLEN, Mason, Okla. Mr. Allen's invention provides a planter which will plant the seed at varying depths and thereby secure a better stand As with this planter some of the seed are planted near the surface, while other seed planted nearby are planted an inch deep, the farmer using this planter will be certain in all cases of obtaining a good stand no matter what the weather conditions may happen to be.

GANG AND MOTOR PLOW.—E. B. SELLARD, 618 Franklin Ave, Mexico, Mo. The object of the invention is to effect an improvement in means for attaching, suspending, and adjusting plows with reference to a frame supported upon wheels which is supported on wheels When an obstruction is met, the plows and frame rise until it is passed, when they resume their proper position

GEARING FOR MOTOR DRIVEN PLOWS.—E B SELLARD, 618 Franklin Ave., Mexico, Mo In order to provide for driving a plow at high or low speed and steering the plow by power as well as by hand, Mr. Sellard connects the motor by sprocket gearing to the countershaft, which in turn drives a supplementary shaft, a double clutch being employed that will throw either a step-down or a step-up gearing into action. The traction wheels are driven by the supplemental shaft through a pair of clutches, either one of which may be disengaged to release the wheel it controls, and thus permit of steering the plow by motor power

Of General Interest.

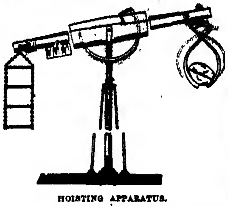
PORTABLE DERRICK.—M. G. BEAN, Walcott, N D This derrick is capable of being carried around by hand or on wagons and handled preferably by one person. It comprises a pair of posts swiveled relatively to each other and adapted to be folded to different angles relatively to each other for different purposes and embodies a number of structural improvements whereby its efficiency as a derrick and its compactness and adaptability are greatly increased.

CREDIT ACCOUNTING APPLIANCE.—A. L LAMBERT, Concordia, Kan. The intention in this case is to provide an appliance more especially designed for the use of merchants, to keep the accounts of customers who buy on credit in a very simple and accurate manner, to allow a salesman to readily ascertain the customer's account, and to permit such salesman to make additions to the customer's account

BOX.—W S ADLER, care of Empire Plow Co, Cleveland Ohio. One purpose of this invention is to provide a box having a plurality of shelves movable relative to one another so as to expose simultaneously the contents of all the shelves, which can be folded up in a convenient air tight manner, so that the contents will be protected from dust and dirt and kept perfectly fresh

MOLD.—H W STRIETELMEIER, Route No 2, Linton Ind The object here is to provide a mold more especially designed for making concrete fence posts and like articles, and arranged to allow convenient and secure removal of the post after being molded to permit immediate re using of the mold for forming another post while the first one is setting.

HOISTING APPARATUS.—F. M. DAUGHERTY, Byron, Wash. This invention relates to hoisting apparatus for handling bags or bales, or other merchandise, and has reference more particularly to apparatus of this class which comprises a beam, means associated therewith for holding a load, means for gravitationally operating the beam to raise the load, and automatic means controlled by the load-holding means for locking the beam against movement in one direction. Besides



HOISTING APPARATUS.

being useful in warehouses, it can advantageously be used in lifting and transferring weights from point to point. The engraving shows a side elevation of an embodiment of the invention, having parts in cross section and parts broken away.

DRYING TABLE.—F. I. BURCHER, care of Acme Cloth Shrinking Machinery Co., 11 E. 4th St., New York. The cloth in the piece is passed over the table to dry before shrinking it, the table being arranged to insure uniform drying of the fabric with the greatest economy of steam used as the heating medium, the table being made in sections capable of being readily set up, or taken apart for packing in a small space, for shipping, storing, etc.

Heating and Lighting.

INCANDESCING ELEMENT.—D. J. MONOSMITH, Spencer, Ohio This inventor has produced an incandescing element made up of laminæ or plates, each plate being weakened by aid of score lines so as to cause the plate to break along said lines if it breaks at all, thereby preventing fracture of the element along any line or plane except one parallel with said score lines or with plates.

Household Utilities.

TEA BREWING APPARATUS.—C. A. SHERMAN, 381 4th Ave., Manhattan, N. Y. This invention provides an urn composed of two independent units, in the upper one of which the tea or other infusion may be brewed and directly withdrawn from the same; or the infused liquid may be withdrawn from its contact with the tea or other substance from the lower unit or receptacle.

Machines and Mechanical Devices.

MATCH MAKING MACHINE.—S. E. RAHR, 918 Madison St., Brooklyn, N. Y. This invention relates to match making machines having an endless chain of carrier plates for securing the splints and carrying the same from device to device for automatically completing the matches and finally ejecting the same

Pertaining to Vehicles.

DRIVING GEAR FOR MOTOR VEHICLES.—O. J. GRAN, Callahan, Cal. This improvement provides a driving gear for automobiles and other motor vehicles, arranged to transmit the power applied by the motor to the rear axle to the front axle without interfering with the steering gear, to compensate for the variation of speed of the front or steering wheels when turning from a straight path, and to prevent skidding.

AUTOMOBILE.—W E. STANLEY, care of Bank of Bay Biscayne, Miami, Fla. In this vehicle the frame carrying the motor may be raised considerably above the ground and be supported in this position, so that the plow shares or shovel members may be carried between the wheels and below the frame, to work the soil as the automobile is driven by its motor. The machine may readily be converted from a pleasure vehicle to one carrying plow shares for working the soil, and cultivation of tall crops.

NOTE.—Copies of any of these patents will be furnished by the SCIENTIFIC AMERICAN for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper

NEW BOOKS, ETC.

ENGINEERING FOR LAND DRAINAGE. A Manual for the Reclamation of Lands Injured by Water. By Charles Gleason Elliott, C.E. New York: John Wiley & Sons, 1912. 12mo.; 339 pp.; illustrated. Price, $2.

The United States have before them greater drainage problems and possibilities than any other country of the world. Since the drainage of the tract now known as Central Park, in 1858, progress in land reclamation has been steady. The work issues increasing calls for the drainage engineer, and students will find in this concise text much needed information. Fieldwork equipment, engineering technique, the preliminary survey, underdrains, flow in open channels, the location and construction of open ditches, levee systems, the reclamation of tidal lands, the drainage of irrigated, peat, and muck lands—all these phases of the subject are set forth, with useful tables, and instruction as to making close estimates and keeping adequate accounts and records.

DREDGES AND DREDGING. By Charles Prelini. New York: D. Van Nostrand Company, 1911. 8vo.; 279 pp.; 82 illustrations. Price, $3 net.

The first power dredge of which we have any knowledge was designed by one Cornelius Meyer in 1685. It utilized horses in the construction of canals and dykes in Holland. It is a far cry from that clumsy and inefficient piece of apparatus to the marvelous machinery of the modern dredge, which has made possible so much of our present commercial development. The debt of navigation to the mechanical digging machine exceeds only that of drainage and irrigation, water supply and mining. All are under heavy obligation to the dredge for the breadth of their accomplishment. The volume in hand treats of this important subject from all points of view—the nature of soils encountered, the method of taking soundings and hydraulic surveys, the excavation of subaqueous rock, the types of dredges employed in various works and their classification and capacity, hydraulic and pneumatic dredges, dipper and grab dredges, and cost data The engravings show plainly the distinctive features of the various types and the relation of these features to the work performed. Mr. Prelini has given us a book that is instructive and fascinating in a very high degree.

COMMENTARY ON THE SCIENCE OF ORGANIZATION AND BUSINESS DEVELOPMENT. By Robert J. Frank, LL.B. Chicago: Chicago Commercial Publishing Company, 1911. 8vo.; 280 pp. Price, $2.75.

The author states, and the facts sustain his contention, that a business soundly founded is at least one third a success: the other two thirds being acquired by opportunity and adequate facilities. It is more essential than the average incorporating group realizes that it should clearly understand the advantages and limitations of a corporate body, and the specific advantages which they desire to enjoy: otherwise it remains for future disagreeable developments to enlighten them as to the errors of their initial step. It is not sufficient, as the author emphasizes, that they rely wholly upon the judgment of counsel The treatise covers in a common sense manner all the usual considerations confronting the organizers of a business corporation. Financing, management, reorganization and consolidation, are plainly set forth, and the promotion of enterprises fittingly receives a separate chapter An appendix contains contract forms, certificates, by-laws and resolutions, a synopsis of the corporation laws of those States most lenient toward this form of organization, and rules for listing stocks and bonds, with a table showing their earnings Incorporators, officers and directors, financiers and accountants will all find this work a reliable desk guide.

WARSHIPS AND THEIR STORY. By R. A. Fletcher. London, New York, Toronto, and Melbourne: Cassell & Co., Ltd., 1911.

In writing this work the author disclaims any intention of treating of the structural problems relating to warships, or intricate matters of strategy and tactics, his aim having been to describe in popular non-technical language the more important types of warships favored at different times in different parts of the world. He shows how type has succeeded type, and he describes the main lines of divergence and development. The author reverses the usual practice of treating the warships as incidental to the naval battles, preferring to treat the naval battles as incidental to the warships. The work opens with an introduction, which forms one of the most readable and instructive chapters of the book, and is in fact a digest of the volume which follows The historical chapter tracing the development of the warship, from the ancient Egyptians to the day of the introduction of artillery, is particularly readable, as are the chapter on iron ships of war and that dealing with guns, projectiles, and armor. The work is written for the layman. It gives him the kind of information he wants, and gives it in an interesting way. The author has done his task well The half-tone work of the book is particularly good, and the subjects of illustration are well chosen

A SHORT COURSE IN GRAPHIC STATICS. For Students of Mechanical Engineering. By William Ledyard Cathcart and J. Irvin Chaffee, A.M. New York: D. Van Nostrand Company, 1911. 12mo.; 133 pp.; 56 illustrations. Price, [illegible] net.

The Efficiency of the Large Manufacturing Plant

By Sidney Graves Koon, M.M.E.

READING between the lines of the census bulletin detailing manufactures in New York State, one of the first State reports issued, and covering 16.3 per cent of the total manufactures of the United States, a number of interesting facts are disclosed. It is found, as was to have been expected, that the proportionate output of large establishments is increasing, while that of small plants is decreasing. It also appears that the efficiency of production in the large plant is much higher than in the small one, more product per man is turned out, and (what is of greater real importance) a larger value per man is added to the product as a result of the manufacturing processes. And this "efficiency" has itself shown a marked increase during the five years between 1904 and 1909, covered by the census investigations.

The first item mentioned is due to the concentration of effort and capital, in small plants and small industries as well as large ones, to combinations of men and enterprises, to the rapidly developing idea in manufacturing which has been so aptly expressed in the State motto of Kentucky: "United we stand; divided we fall!" Co-operation is the keynote, and it is finding expression in establishments of all sizes. So it follows that the ratio of the output of the large plants to the total output is increasing.

Plants with an individual annual product of $1,000,000 or more numbered 294 in 1904 and 470 in 1909. They employed 20.9 per cent of the total number of wage earners in 1904 and 25.4 per cent in 1909. They furnished 32.8 percent of the products in 1904 and 37 per cent in 1909. They added value through manufacturing processes amounting to 25.9 per cent of the total in 1904 and 31 per cent in 1909.

A comparison of these figures will show that these large plants produced about 50 per cent more output per man than the average of all plants, and 80 per cent more than did the 40,000 smaller plants. In value added through manufacture, the large plants showed 23 per cent more per man than the total average, and 32 per cent more than the smaller plants. This establishes our second point, the increased economy of operation of the large plant. And it is due in large measure to better facilities for handling materials, cranes and other labor-saving machinery, improved railroad connections and service, and less of the "jack-of-all-trades" in the make-up of the "hands." To what extent the new fad "scientific management" has influenced this result is problematical.

The general gain in efficiency all along the line is shown by the figures for all the five groupings given in the census bulletin, plants with less than $5,000 output; between $5,000 and $20,000; between $20,000 and $100,000; between $100,000 and $1,000,000; and over $1,000,000 annually. The gain in the establishments as a whole was from $2,904 product per "hand" in 1904 to $3,356 in 1909, an increase of 15.6 per cent. In value added during the processes, the gain per hand was from $1,330 to $1,507, or 13.3 per cent.

All of these points are best shown in the subjoined table. In the table, all figures for total values of products and total values added, represent millions of dollars. The total products amounted to $3,369,490,192 in 1909 against $2,488,345,579 in 1904, a gain of 35.4 per cent. The total value added in manufacturing increased from $1,139,742,293 in 1904 to $1,512,585,850 in 1909, or 32.7 per cent. The value added represented 45.8 per cent of the product in 1904; 44.9 per cent in 1909.

Annual Product per Plant	Date	Wage Earners	Millions of Dollars		Dollars per "Hand"

Conquering Infection

THE epic work of Gorgas and his associates, by which one of the greatest plague spots on the face of the earth has been turned into a veritable health resort, is now known and appreciated throughout civilization. It is gratifying to realize that like work has been doing in many other tropical regions.

For example, the Gold Coast and other West African colonies have long been branded as graveyards of white colonists. From 1881 to 1897 the white Gold Coast mortality averaged 75.8 in the thousand for each year, in Lagos it was 53.6. Since 1897, however, mosquitoes and rats have been fought on lines laid down by the scientific bacteriologist; water supplies have been purified and protected; and antityphoid inoculations have been made. The result? In the years 1903-1906 the death rate was 24.3; during 1907-1911 it was 17.6; in 1911 it was 13.7. Here is a record fairly emulative of Panama.

India, the home and the source since the dawn of history of many a "world pestilence," has now a standing British army of about 72,000 men, among whom malarial fevers are the most common illness; formerly typhoid was by far the most deadly. Comparatively little progress has been made against the malarias but the enteric diseases have been so well combatted by means of sanitation and inoculations that one might almost be sanguine of their extinction. Five years ago the death rate was 2.66 in the thousand, a marked reduction from former years; in 1910 it was reduced to 1.58; in 1911 it was but 0.63. Nor was all such improvement monopolized by the white residents and soldiers. Among the native Indian troops, which are nearly twice as numerous as the British similar progress has been made. While in the whole native population of "fatalistic" India (which has from time immemorial, up to a few years past, looked upon cholera and the plague as "visitations" it were impious to defy) the death rate in 1910 was 33.20 in the thousand, as against 35.40 in the preceding five years; the birth rate rising *pari passu* from 37.51 to 39.52.

Such achievements as these are in truth but part of a world-wide and constantly more and more victorious fight with disease, and especially with epidemics against which mankind has ever, up to our generation, been almost defenseless. Thus, by reason of the necessities of tropical colonization, are infectious diseases being eliminated from those regions; though of course medical science cannot remedy the high temperatures, which induce in the Caucasian the "tropical wrath," characterized as it so sadly is by intemperance, lassitude, periods of spasmodic mania and of hideously cruel acts toward inoffending and defenceless natives.

When such triumph over disease can be achieved despite the formidably adverse conditions obtaining in the tropics there should be an even greater measure of success in the temperate zone; while failure to eliminate disease-transmitting insects, and to preserve foods and waters pure, must in reciprocal degree be discreditable in those regions of the earth where sanitation is easier to effect and civilization more advanced.

Bacterial Purification of Water and Sewage

(Concluded from page 37.)

Nevertheless, the rural community and the large private estates in the country have similar problems which have to be faced and solved. In the latter case, especially where convenience has demanded an up-to-date water system, there is the greatest need of a careful scientific study to the end that the final disposal of the wastes shall be safe and complete. As a rule too little attention has been given to this phase of the subject by those most interested. It is generally thought sufficient to get the sewage out of sight under the ground somewhere and as long as no obvious nuisance arises, no further thought is given to it. The fact must be borne in mind that the purifying agency of the soil lies quite close to the surface. At moderate depths, these being greater with the more open soils, the air supply is insufficient for the proper action of the bacterial life and the continuous discharge of sewage under ground in such a way that it tends to sink into still lower depth is a mere evasion of the real problem. This sewage mingles with the ground water and will reappear at some point, possibly remote, possibly in the well or spring of the same place, or of a neighbor, but in all cases practically unchanged in character. Examples are not lacking in which disease-producing bacteria have been conveyed many hundreds of feet through compact soil. Several typhoid fever epidemics resulting from such a situation have been recorded. The water and sewage problems of country homes depend upon so many local factors that any general discussion of them would be quite futile. This is a matter, however, which justifies most careful study in each particular case, and the science of sewage disposal has now advanced to such a point that satisfactory and economical solutions are always possible.

Insects and Disease

(Concluded from page 34.)

the non-immune population. Since this mosquito breeds by preference in fresh, clean, quiet water, the first thing to do in attacking this species is to render collections of water inaccessible to the mosquito. These are usually found to be water-containers of various sizes, such as barrels, tanks, cisterns, tin cans, sags in roof-gutters and the junction of the leaves with the stem on plants of the *Agava* family. Breeding places may be screened, drained, salted, oiled, stocked with fish or destroyed.

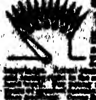
It is also necessary that measures be taken to prevent the mosquito from becoming infected and to this end all cases of fever occurring in the yellow fever belt should be screened for the first three days of illness, and upon the recovery or death of the patient the house should be fumigated to kill mosquitoes. For this purpose, sulphur dioxide, which may be produced by burning sulphur in the proportion of two pounds to the thousand cubic feet of initial air space, is perhaps the best agent. Mosquitoes may also be killed by burning pyrethrum or tobacco, but these latter methods are less efficacious. It should be borne in mind that formaldehyde which is used as a fumigating agent for certain diseases will not kill insects. It is interesting in this connection to note that in those locations in the tropics where yellow fever is endemic the disease is probably kept alive by infants in arms who have it in mild form and thus continue the cycle between the mosquito and the human species.

The yellow fever mosquito is essentially a domestic animal and as far as its relation to the disease is concerned need be considered only in connection with its proximity to the home of man. The malaria mosquito on the contrary does not necessarily live in close proximity to man and will breed in almost any deposit of fresh water which is quiet and not stocked with fish or insects which destroy the mosquito larvæ. The same general methods of extermination as outlined above may be used, but they should be carried on in a

wider radius and should include the drainage of swamps. In addition, the human cycle of the disease may be partially controlled by the daily administration of small doses of quinine to all persons living in the infected zone. Also, it should be the rule to sleep under a well constructed bed-net and endeavor as far as possible to avoid being bitten by mosquitoes at all times. To-day malaria is the great scourge of the tropics. It has laid waste and prevented the occupation by the human species of a greater portion of the globe than any other disease. The Island of Mauritius for example, whose name was formerly synonymous with good health has in recent years had an enormous amount of malaria due to the introduction of the *Anopheles* by ships and the importation of the germ in the persons of immigrants, with the result that what was formerly a great sanatorium is now an endemic malaria focus. Since this disease may be controlled and limited by the extermination of *Anopheles* mosquitoes, it is the duty of communities in which this species abounds to rid themselves of this menace to health and commerce.

Reference has already been made to the rôle of the flea in the transmission of plague. This is of extreme importance because plague is primarily a disease of rodents and secondarily and accidentally a disease of man. Almost every fur-bearing animal has fleas which may be easily infected by the ingestion of infected blood. Thus, it is found that the rat flea, the ground squirrel flea, and the tarbagan flea have all been convicted at one time or another of having transmitted bubonic plague. The remedy is obvious. If the animal carrying the flea which bridges the space between the infected rodent and the well human being be excluded from the home of man there need be little fear of bubonic plague. Therefore, the work which was carried on in California for the eradication of plague was directed very largely at the extermination of rodents This may be accomplished by a simultaneous attack upon the home and the food supply of the rat and by killing them by the use of poisons and traps. Plague is out upon its march around the world, and for the past five years has been making a steady advance up the Spanish main Very recently it has appeared in Porto Rico and for all we know it may now be smouldering in the rodent population of some of our large Atlantic seaports. If a survey of these rodents is made now and the foci of infection stamped out much money and many lives may be saved in the future. This is a measure of immediate necessity if we would protect our sanitary and commercial interests.

Not the least interesting aspect of the transmission of disease by insects is the rôle played by the tick in this regard. One species of this insect is known to carry African tick fever and we have a strictly American disease almost wholly confined to the Western States, Rocky Mountain tick fever, which is carried by another species, the *Dermacentor andersoni*. The organism of this disease has not yet been discovered but the season of its prevalence is coincident with the period of greatest tick prevalence and it is found only in those localities in which ticks occur. Two types of Rocky Mountain spotted fever are known. The mild, which occurs in Utah, Wyoming, Idaho, Nevada and eastern California, Oregon and Washington, and the severe form, which is found in Montana. Usually the disease is confined to one side of a valley and in almost every instance there is a history of the patient having been bitten by a tick. Further, the disease has been experimentally transmitted from one human being to another, from human beings to guinea pigs, and from guinea pigs to guinea pigs by the bite of the tick. Active work is now being carried on in Montana by the United States Public Health and Marine Hospital Service for the eradication of the disease. The general plan of operation includes the extermination of the small mammals on which the tick lives during the earlier portion of its developmental cycle and the "dipping" of the domestic stock on which the ticks spend a portion of their adult life in antiseptic solutions. Also, the land on which



locality. This work has been in operation for only a single summer, but it has resulted in the total cessation of cases in what was hitherto a badly infected locality.

Typhus fever, which also goes by the names of "jail fever" and "ship fever," and which in former years was regarded as the inevitable companion of war and famine, until very recently, was thought to have entirely disappeared from our country. It has, however, continued in Mexico where the researches of Nicole, Ricketts and Wilder, and Anderson and Goldberger have demonstrated that it is carried by the body louse, the *Pediculus vestimenti*. Recently Anderson and Goldberger have demonstrated that the head louse, *Pediculus capitis*, may also transmit the disease. More important than all, Anderson and Goldberger, working in the Hygienic Laboratory of the United States Public Health and Marine Hospital Service at Washington, D. C., have proven the identity of Brill's disease, a wide-spread disease in the United States, with typhus fever. It is thus seen that typhus fever of a mild type is prevalent in the United States. Since the disease is carried by lice, and since lice are the almost inevitable companions of filth and squalor, it is seen that the best way to prevent this disease is to kill lice, and by cleanliness to render their environment unsuitable for their existence. Brill's disease, or mild typhus fever, occurs often in children. Lice are found often on children. Lousy children should therefore be excluded from school until they have been freed from this disgusting parasite.

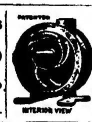
It is not at all improbable that bedbugs also carry disease. While this has not been proven definitely there are numerous instances on record in which the evidence tends to incriminate this species. The remedy is apparent.

The Destruction of the "Schwaben"

THE old wooden airship shed at Duesseldorf is fast gaining a reputation as the aerial "hoodoo dock." When everything about the Zeppelin ships appeared secure at last, after four of them had been making record trips, the "Schwaben" (fortunately insured at her full value against fire) was destroyed as if by a bolt from a clear sky, after her 214th passenger trip, in close proximity to the same Duesseldorf shed that twice wrecked the "Deutschland." She was at anchor, weathering a storm for hours, and trying to avoid a risky entrance into the shed, when a severe gust raised her into the air, broke her back and ignited the escaping gas, presumably by frictional electricity.

The disaster must be ascribed to the over-confidence inspired by handling the ship safely in so many stormy landings, and to the treacherous nature of the wind, which, as aviators well know, may all of a sudden show quite unfamiliar antics and effects. Again the lesson was emphasized that men, even in great numbers, cannot replace reliable anchors. The four concrete blocks sunk into the ground, around which the ship swings like a weather vane, held by a swivel at the ends of four converging cables, were not in use, because these are placed farther from the shed to give room for the ship's movements.

The least expensive way to make old sheds like that at Duesseldorf safe, would be to erect one of those anchoring towers of steel lattice work which have been often suggested, and around which the ship at anchor could swing in safety, clear of the ground, until the wind's subsiding permitted the safe entrance into the shed. The English army has tried this plan with excellent success on a small scale. An interesting feature of the "Schwaben's" disaster is its resemblance to certain aeroplane accidents. The breaking of the airship's back was due to the same causes that have stripped monoplanes in the air of their wings—the great resistance of the inertia of concentrated weight against yielding under a very sudden and heavy wind pressure. It could have been avoided by lightening the cars [illegible]



This would have equalized the strain. If the weight of the passengers had still been in the cabin, possibly nothing would have happened, for the airship did not really break away, as otherwise the men holding it would not have been burned. Such "explosive" lifting effects of wind gusts can also occur only near the ground and near obstacles like the shed, where the gust may "jam" under the ship. It should be noted that the "Schwaben" was not pushed back, but lifted straight up like an aeroplane. It would do no harm to relieve the cars in future of all tanks, stores and other weights that can be possibly arranged along the passageway, as already done in the Siemens-Shuckert dirigible, although there is ample strength for free flight.

If there had been no smashing there would have been no escaping gas and no electric sparks to ignite it. But a water sprinkling device (tried on the "Suchard") inside the hull and above the ballonets could easily guard against frictional electricity in critical situations, and German manufacturers are now hard at work upon a balloon cloth that cannot be electrified by friction or concussion even in dry air.

The Current Supplement

IN this week's SUPPLEMENT, No. 1906, Arthur J. Hoskin discusses very lucidly the legal and technical points which require consideration in connection with the opening of new mines.—C. M. Chapman writes on Methods for Testing Coatings for Cement Surfaces.—A richly illustrated article by L. Claremont tells our readers of the wonderful gem industry carried on by the natives in Ceylon.—The benefits to mankind which have been gained by experiments upon animals cannot be brought with too great emphasis before the public. Much has been written on the subject, but the article which appears in our current issue is one of unusual merit and persuasive force and should be read by all, especially by those who perhaps may not be very fully informed on the subject and may possibly still entertain some doubt regarding the great gains which medical science has to record in this quarter.—Day Allen Willey contributes an illustrated article on the remarkable engineering feat accomplished in the building of a railway in ice-bound Alaska.—A report of some tests of a simple engine taking steam at less than atmospheric pressure is of particular interest in connection with the utilization of solar energy.—Dr. Zahm, the noted American authority, contributes a masterly article on Elements of Theoretical Aeromechanics, which will run as a serial through two or three issues.

Centennial of Gas

WHEN and where gas was first used, it seems to be difficult to ascertain. Yet 1912 is regarded as the one hundredth anniversary of the introduction of illuminating gas. Apparently the event to be celebrated is the organization in 1812 of the London Gas Light and Coke Company. Gas, however, was used for illuminating purposes long before. Murdoch used it for lighting as early as 1795 and perhaps earlier. At all events, in 1798, he put up a gas plant for Boulton, Watt and Company, in Soho. The American city of Baltimore is credited with being the first to apply illuminating gas practically to general illumination. There was a small plant in Newport, Rhode Island, as early as 1813, which antedates the Baltimore plant by eight years.

Tunnels in Constantinople

IT is reported that the Turkish council of state is studying a plan for an underground railway to connect Stamboul with Pera, under the Golden Horn. A more ambitious plan, which English engineers are said to have in hand, contemplates a double tube under the Bosporus, between the extreme points of Stamboul and Haidar Pasha, to connect the railway systems of European and Asiatic Turkey.

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are *sharp*, the articles *short*, and the facts *authentic*, the contributions will receive special attention. Accepted articles will be paid for at regular space rates.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

Human Fallibility and the Automatic Stop

THE theory of the automatic block signal system as applied to railroads for the prevention of collisions is perfect. Its practice as carried out day by day on the railroads of the country, proves that it is not the absolute preventive of collision which we hoped it would prove to be. From time to time there have occurred serious railroad disasters which an effective working of the block signal system should have rendered impossible. The latest and most frightful of these were the rear end collisions at Corning, New York, and Latrobe, Pennsylvania, when nearly one hundred people lost their lives, and an even larger number were injured.

It is not sufficient to say that these accidents were due to the human element, which can never be controlled by any mechanism, howsoever ingenious and effective it may be. A block signal system, if it is to do its work, must make it impossible for two trains to be in the same block at the same time. This, the present system cannot do in those cases where there is negligence on the part of the operating staff.

In the Corning disaster, the engineer ran by two block signals, and appears to have taken no notice of a third signal, placed in the rear of the stalled train by the brakeman. In this case, the collision was due either to the carelessness, wilful disobedience, or mental and physical incapacity of the engineer. Just how he came to run by these signals will be shown during the official investigation.

The point we wish once more to emphasize is that the block signal system, as at present laid out and operated, is not absolutely effective. It lacks one element, simple and readily installed, which, if it were present, would render block signalling absolutely effective as a preventive of collision. We refer to the automatic stop.

The automatic stop is as essential to a properly-constructed block signal system as the trigger is to the gun. This gruesome Corning disaster simply emphasizes a fact which this journal has many times proclaimed in the past few years, namely, that the excellent idea embodied in block signalling can be made absolutely effective only by rendering it mechanically impossible for a train to run by a signal.

It is "up to" the railroads to install the stop on all important lines carrying mixed traffic. At present they do not look favorably upon this mechanism. They dislike the first cost and they have an equal dislike for the cost of maintenance.

We commend to the consideration of the Interstate Commerce Commission—that fine body of men which is doing such magnificent work, both for the railroads and its patrons—the necessity for the installation of the automatic stop on all important lines carrying a heavy and mixed traffic of express and passenger trains. The device should be so arranged that when the semaphore arm is up, the trip will be up. Moreover, the trip should operate to close the throttle and apply the brakes simultaneously. Also there should be some self-locking recording arrangement, by which the locomotive, when it has been tripped carries back to the round house a visible record of the fact that the engineer has run by a signal.

Railroad managers complain bitterly of the lax ideas of discipline which prevail among the operatives of American railroads, and name this as a fruitful cause of accidents. The best corrective is to place the careless operator under automatic control.

The Fate of Vaniman

ALTHOUGH there was no survivor to the dreadful catastrophe that blotted out what has been the most determined attempt so far to supply America with at least one dirigible of businesslike proportions, it is by no means so difficult to point out defects in the "Akron," which rendered it liable to such an accident.

Building a dirigible balloon of large size is a problem that bristles with engineering difficulties, especially if the balloon is to be non-rigid, as was the "Akron." It calls for a man who is not only a clever mechanician and inventor, but an architect and civil engineer of high order.

The large European non-rigid dirigibles have been developed step by step. The first Gross, Parseval, and Lebaudy airships were very small; the first "Ville de Paris," a mere enlargement of the Santos Dumonts, was a complete failure.

Vaniman began with the size of almost the largest European non-rigid dirigibles. It did not follow any European model. The shape of the envelope did not show any "speed lines" (such as those developed in the laboratories of Europe); there were no adequate steadying fins; the rudders were too small; and while the 280 horse-power propelling plant was rather weak for the displacement so that the speed could only be quite moderate, there were no aeroplanes to counteract the changes in the gas lift, as in the large French dirigibles with moderate power.

We must remember, however, that the "Akron" was not built to sail over land, which explains the departure from European design. It was intended particularly for a transatlantic venture, and as economy of fuel was a vital factor, Mr. Vaniman intended to drift as much as possible. To attempt to drive the airship across the ocean at a speed of forty to fifty miles an hour, such as attained by European dirigibles, would have required more fuel than he could very well have carried. Mr. Vaniman was, therefore, trying to build a new type of airship which we may call a "drifting dirigible," contradictory as the term may seem. Such being the case it was not necessary for him to use more than one or possibly two engines at a time, as he desired to make little more than steerage way. With a weak power plant and a machine that was to be blown by the winds, the "aeroplane lift" idea was discarded. Instead, Mr. Vaniman depended upon driving his airship down by means of orientable propellers and also by pumping air ballast in the ballonets until he could come near enough to the surface of the sea to pick up water ballast in his "hydroelevator."

It is probable that Vaniman, when he found the hot July sun squeezing all the air out of the air ballonets, against the heavy weight on their safety valves, and trying to expand the gas still further, depended on preventing further ascension by keeping the gas forcibly in the envelope under compression. Just why he did not drive the machine down with his orientable propellers who can say? He had two sets of them, one pair driven by an 80 horse-power engine and another by an engine of 200 horse-power. It was the first ascension of the "Akron" on a hot summer day. Accounts clearly establish the fact that the airship, when the sun gained its full power, began to rise steadily until everybody wondered about the unprecedented and uncalled for altitude. It ascended until all the air was forced out of the ballonets; then it burst. It is now evident that the first reports were erroneous. The gas was not set on fire. The uncharred envelope is conclusive evidence of the fact that fire played no part in the catastrophe.

The whole occurrence is a close parallel to the fate of Oskar Erbslöeh's dirigible in 1910, that burst in the air, when it suddenly emerged from a dense fog into sunshine, killing all aboard. Only in Vaniman's case it came more gradually; in place of a German fog there was the characteristic American summer haze which greatly influences radiation. The higher the "Akron" ascended the more the haze thinned, and the more powerful became the sun. At this moment Vaniman ought to have pulled the valve cord energetically, but it is doubtful whether he realized how much discretion is required in piloting large, non-rigid airships. It is doubtful whether Vaniman watched his pressure gages with the unceasing vigilance which is a point of honor among Parseval captains; it is doubtful whether he had any experience as to how easily they may get out of order, unless carefully looked after (their many long, thin tubes have a trick of getting entangled and choked); it is even doubtful whether there were any such gages at all, for there was one required for every air ballonet, of which Vaniman had so many, and two or three for the gas space, and very probably he disliked the complication and depended instead on a solitary safety valve.

But, having no aeroplanes, unless he had tons of ballast, Mr. Vaniman had a reason for not opening the valve. After the high ascension a fall into the water was very likely to follow the escape of gas, and it was quite logical thus to apply to some extent the principle of the proposed "steel envelope" even to the "Akron," for the strength of whose tough silk envelope Vaniman had given as high a figure as an inch and a half of water. But without a sufficient number of absolutely reliable pressure gages, this was extremely dangerous.

Another point must be considered. The hydrogen-generating facilities at Atlantic City were rather primitive. Any remnant of acid vapor in the gas has a very fatal influence in weakening an airship's envelope. The European "giants" do not use any hydrogen made by the old acid process.

Finally, it should be pointed out that the system of air and gas valves required in a large, non-rigid airship is as formidable an engineering problem as the valves of a gasoline motor. But where a gasoline motor gets stalled when its valves fail to work properly, an airship may burst or fail.

It seems tragical that Vaniman, who has displayed exceptional ingenuity in many details, should have fallen a victim to the neglect of proven facts.

At the same time the actual cause of the disaster may have been something that we have not touched upon. Consider the first trial trip of the "Akron." Who but an eye witness could explain that the failure was due to the accidental dropping of a bag of sand on the water circulating pipe of the engine?

The Latest Triumph of Organic Chemistry

IF proof were needed of the fertility of chemical science as a source of material gains, such proof comes in most convincing form by the recent announcement of the successful completion, by a commercially sound process, of the synthesis of India rubber. The importance of this new trophy of the organic chemist requires no emphasis: the general public is well aware of the great demand for rubber, and the difficulty which has been experienced in meeting it. Prof. Hinrichsen, on another page of this issue, gives us some statistics illustrating this point.

The announcement of the synthesis of India rubber comes from the mouth of Prof. W. H. Perkin, son of the illustrious Sir William Perkin, founder of the coal tar dye industry. Mr. E. H. Strange, of the firm of Strange and Graham, of London, England, some time ago organized a group of investigators for collaboration on the problem of synthetic rubber. The list included, in addition to Prof. Perkin, Sir William Ramsay, Prof. Fernbach, of the Pasteur Institute of Paris, and Dr. F. E. Matthews. That a certain hydrocarbon, termed isoprene, was obtainable from rubber, and could, under favorable, but somewhat ill-defined conditions, be reconverted into rubber, had been known since 1875. It remained to find a cheap source of isoprene and to discover the exact conditions under which its polymerization to rubber could be positively and rapidly brought about. Both these problems have been solved by the group of chemists organized by Mr. Strange. Prof. Fernbach, as a result of some eighteen months of arduous research, has finally perfected a fermentation process by which starchy materials (a kind of skilly made from Indian corn or potatoes and water) are converted into fusel oil. The higher alcohols which are separated from this by fractional distillation are converted into isoprene by successive treatments with hydrochloric acid, chlorine and soda lime, and the polymerization is brought about by contact with metallic sodium. This reaction was accidentally discovered by Dr. Matthews, who left some isoprene in contact with metallic sodium in July, 1910, and on returning from a vacation in September found that the isoprene had turned into a solid mass of rubber.

As regards the cost of the new process, while of course at the present stage it is impossible to give any very reliable figures, the preliminary estimates are most encouraging. We are told that the higher alcohols separated from the fusel oil can be obtained at a cost of not more than $150 a ton, and it is expected that the synthetic rubber may be sold at about 60 cents per pound. Inasmuch as para rubber is now selling at $1.35 per pound, the manufacturers of synthetic rubber evidently have every cause to take an optimistic view of their prospects. It would, however, be premature to make any very positive statements with regard to the commercial situation.

It seems fitting that the name of Perkin should be associated with this achievement. Those who are familiar with the history of modern industrial chemistry know that England may well be said to have been its birthplace. It was Sir William, also Perkin, who laid the foundation stone of the edifice of the coal tar industries, which have since been reared to such magnificent proportions chiefly by German chemists and capital. In the synthesis of rubber a close race has been run, in which our English cousins have won, their German competitors coming in as a close second; Prof. Harries's independent discovery of the polymerization of isoprene, though published first, was actually made months later than that of Dr. Matthews.

Engineering

Increase of the Japanese Navy.—We understand that the Minister of Marine in Japan is in favor of the building of 15 dreadnoughts of the largest size, the construction to be spread out over the seven years from 1914 to 1920. Rumor has it that in addition to the four 27,500-ton battle-cruisers now under construction, six other vessels of this class will also be built.

Warship Iceberg Warnings.—The cruiser "Birmingham" is doing good service as an ice patrol on the northern steamship route across the Atlantic. Recently this cruiser sent a radiogram, announcing the presence of three large bergs three miles west of latitude 43.03 and longitude 49.53. It stated that another large berg had been seen fifteen miles to the southwest. The reports are sent to the Navy Department and thence to the Hydrographic Office.

American Shipbuilding.—Last year's shipbuilding, according to the statistics of the Bureau of Navigation, accounted for 1,702 new merchant ships of all descriptions, aggregating 243,792 gross tons, as compared with 1,308 ships of 203,158 gross tons, built during the year preceding. Thirty-five steel vessels were built on the Great Lakes, including two of 8,603 gross tons, the largest vessels in the lake service. Fourteen steel vessels of 30,039 gross tons, were built for the Atlantic service.

Two Battleships a Year.—It is gratifying to notice that the press of the country is supporting the United States Senate in its stand against the House of Representatives in the matter of the increase of our battleship strength. Thus, the Rochester *Times* points out that a programme of two battleships a year will not even enable this country to maintain its relative naval strength, and the San Diego *Union* shows that failure to make the customary addition of two battleships a year must ultimately cause the United States to drop from its present position to that of fourth or fifth among the naval powers.

Steady Rise of Gatun Lake.—We noted recently that two sluice-gates in the spillway dam at Gatun were opened on June 5th, when the lake stood at an elevation of 26.5 feet above sea level. These gates were closed on June 19th, and in the week following the lake had risen to elevation +29.37. The lake may now rise to an elevation +37 feet, 4 inches, at which level it will reach the sills of the guard gates of the upper locks at Gatun. It is expected that these gates, in both the easterly and westerly flight of locks, will be completed and closed before the water reaches the sills, in which case the filling of the lake may proceed continuously throughout the rainy season.

The Ever-present Rail Peril.—H. W. Belknap, Chief Inspector of Safety Appliances of the Interstate Commerce Commission, in his report on the cause of an accident on the Great Northern Railroad on December 30th last, after calling attention to the constantly increasing number of rail failures, due generally to structural defects, says "present specifications and tests, in so far as the detection of longitudinal seams within the rail is concerned, appear to be inadequate. It seems to be time that some definite action were taken toward eliminating this source of danger and securing structurally sound rails." The cause of the accident referred to was, primarily, a defective and seriously seamed 80-pound Bessemer steel rail.

Channel Steamers With Geared Turbines.—The new Channel steamers "Normannia" and "Hantonia," built for the London & Southwestern Railway Company, have been equipped with geared turbines, using a gear of the same general type as the Melville-McAlpin. They show a consumption per shaft horse-power per hour of 1.34 pounds of coal, when the vessels are being run at a maximum speed of 19 to 20 knots. The water consumption for the geared turbines was 12 pounds per horse-power per hour, as compared with 15.1 pounds in similar turbine-driven steamers of about the same size and speed, which use a direct drive. Careful observation in the passenger quarters failed to reveal any inconvenience of vibration or noise due to the mechanical reduction gear.

New Haven Electrical Equipment.—According to Mr. W. S. Murray, Electrical Engineer of the New York, New Haven and Hartford Railroad, the power house for its electrified lines between Stamford and New York has a capacity of 45,000 horse-power for the generation of single-phase current. In 1912, 562 miles of track will be electrified, including tracks in yards and the four-track system from beyond Stamford to New York. The locomotive equipment, including multiple-unit motor-cars, will be 151 units, of a total capacity of 126,800 horse-power. The investment cost of the system, which is single-phase current, will be between 75 per cent and 80 per cent of the cost of an equal direct-current electrification. Mr. Murray claims that the all-day efficiency of his system is 15 per cent higher than that of a direct-current, third-rail system.

Electricity

Sheep Shearing by Electricity.—A novel application of electric power is that of shearing sheep and clipping horses. The apparatus consists of a suitable electric motor connected by a flexible shaft to the ordinary shearing tool. The motor is of the two-speed type, and can be employed also to drive a rotating brush for grooming horses, or a small emery wheel for grinding the clipper combs.

Effect of Light on the Resistance of Selenium.—The effect of light on the resistance of selenium is well known, and has been made the basis of photo-telephonic devices for transmitting sound-waves over a beam of light. It has recently been shown that the changes of conductivity in a certain variety of selenium can be explained by assuming that the light penetrates to some distance into the conducting layer. The effective depth of penetration is about 0.014 millimeters, and filing or sandblasting the selenium surface increases the conductivity.

High-voltage Transmission in England.—A pioneer installation of the Thury direct current series system of electric power transmission in London has been running steadily for about fifteen months. In this system direct current at high voltage is transmitted by two single-conductor paper-insulated underground cables. The circuit is "all-metallic" normally, but in case of breakdown of one of the cables the earth can be used as a return conductor, by permission of the municipal authorities. The cables are, however, designed to carry 100,000 volts, with special precautions against breakdown at the joints. A number of generators in series are used, having an electromotive force not exceeding 5,000 volts each, which is regarded as the limit of safe working on a single commutator.

The Magnetization of Permanent Magnets.—In the course of a lecture at the recent meeting of the British Institution of Electrical Engin... held at Glasgow, Dr. Sylvanus Thompson stated tha... permanence of magnets depended on the quality of ... steel, the shape and dimensions of the magnet, the heat treatment, the maturing, the method of preserving the magnetism ("aging"), and, least important of all, the manner of magnetization. The remanent magnetism of short bars is less than that of long ones: "Short bars have no memory," as Lord Kelvin put it. A good permanent magnet steel should retain an intensity of magnetization of about 1,000 C. G. S. units, and the coercive force increases with the carbon content of the steel. The lecture included a masterly review of the properties of steel as revealed by its microstructure.

Study of Commutation by the Oscillograph.—The oscillograph study of the generation of electromotive force and current in the armature coils of electric generators gives valuable information on the proper setting of brushes, the location of interpoles, etc. A new method of studying commutation by the oscillograph is suggested involving the use of a special armature coil wound in the same slots with the working armature coil which it is desired to study and terminating in slip rings for making contact with the oscillograph circuit. It is proposed to provide an "indicating coil" of this kind, not only on special generators for teaching purposes, but also on all large machines, and on all machines working near the limits of commutation, in the course of the construction of these machines; just as the steam engine builder always provides indicator cocks on his engines.

French Aeroplane Wireless Experiments.—Some very successful experiments were made with wireless telegraphy upon aeroplanes in France at Chartres, using a biplane mounted with the new type of transmitter designed by M. Rouget. The aeroplane started from the aerodrome at Chartres with the inventor on board, piloted by Frantz. In all, a flight of about 100 miles was made, around the country, with 30 miles as the greatest distance from the center. A small wireless post had been put up at the aerodrome and the army officers thus kept in touch with the flyer. The antenna at the ground post was less than 100 feet long and was stretched at a height of 30 feet. The officers could take all the observations made by the pilot *en route* and the signals were quite clear. On the aeroplane the apparatus used an antenna wire about 100 feet in length, hanging down from one end, and the musical spark method was employed. The wireless apparatus, together with a miniature dynamo, weighs but 70 pounds. The small alternator of 200 watts and 110 volts is coupled to the aeroplane motor directly, by means of a new clutch coupler. A small transformer raises the voltage and thus supplies 30,000 volts to the apparatus for charging the condenser. In M. Rouget's new design, all the high tension wiring is localized in a small space so as not to endanger the pilot, as was heretofore found. The transformer is hermetically imbedded in a box with paraffine. The hanging wire of the antenna can be reeled up in 15 seconds. A safety device can cut off the wire should the aeroplane descend very rapidly in case of accident.

Aeronautics

A New Altitude Record.—At the International Aviation Meet held at Vienna, Csakay (the assumed name of Lieut. Miller) reached an altitude of 13,779 feet on June 29th with a passenger. The best previous altitude record with a passenger is that of Prevost at Courcy, 6,858 feet.

A Wright Memorial Prize.—As a memorial to the late Wilbur Wright the Royal Aeronautical Society is soliciting subscriptions for an annual money prize to be awarded for the best lecture on aeronautics. The lectures will be known as the Wilbur Wright Memorial Addresses.

A Nine-hour Zeppelin Trip.—On June 27th the Zeppelin dirigible "Victoria Luise" made a nine-hour trip with twelve passengers directly out from Hamburg over the North Sea. Starting at 6.15 o'clock in the morning, the vessel passed over Helgoland at 9.15. She landed at Hamburg again at 3.15.

The War Department and Aeroplanes.—It is not probable that any advertisements for the purchase of army aeroplanes will be issued in the near future. The policy of the War Department has been to purchase aeroplanes only from American manufacturers whose products are known to be suitable for military service. Orders have already been placed which will obligate all of the available appropriation remaining on hand and no further purchases can be made until the next army appropriation has been passed and approved.

An Accident Due to Air Wash.—During the first aeroplane meeting held at Rheims, in 1909, aviators for the first time realized the dangers of flying in the wake of an aeroplane. Although the perils that lurk in the wash of a flying machine are fully appreciated, nevertheless a serious accident occurred at Villa Coublay, near Paris, on July 5th last. Lieuts Briez and Burlez of the French Army started on a flight to Belfort, each in a monoplane. Lieut. Burloz had attained an altitude of about 600 feet, passing the other man at greater speed, 100 feet higher, forcing a current of air downward and causing the machine driven by Briez to lose his equilibrium. The monoplane crashed to the ground and Briez ... two broken legs, a fractured jaw and injuries to his che... He is expected to recover.

The Dirigible in Warfare.—The *Slampa* of Turin, says the *Times* correspondent of R..., publishes a dispatch from its special correspondent at Bengazi, Count Savorgnan di Brazza, which furnishes an interesting description of the work of a dirigible in actual warfare. The "P1" left its hangar at 6 in the morning carrying on board the Commandante Peuco and the pilots, Capt. Saymandi and Lieut. Benigai. The object was to carry out an offensive reconnaissance, for which purpose the dirigible was supplied with bombs. Rising over the sea to the height of 1,000 meters, it turned eastward toward Koefia, and, passing over that oasis, was able to ascertain that, for the moment, it contained none of the enemy. Making a wide detour, the "P1" turned toward the south in the direction of Sidi Mufta, in the neighborhood of which, both at the foot of the Djebel and on the plain, the principal tents of the Turk and Arab camp lie scattered over a considerable space of ground. No sooner had the edge of the encampment been reached than a number of little puffs of white smoke were observed on the ground beneath, and the unmistakable crackle of rifle fire made itself heard in spite of the noisy roar of the airship's motor. The Turks and Arabs had begun a violent fusillade against the dirigible, which promptly answered by dropping its first bomb. A flash of fire and a dense cloud of smoke rose well in the middle of a group of tents, from which men could be seen hurriedly escaping. A second bomb followed the first, producing the same effect. The Turks, realizing the futility of their rifle fire, brought their artillery into action. From the edge of the sand-dunes two flashes were suddenly seen, followed by others. Evidently the artillery had been prepared beforehand for this purpose, for the shells, instead of bursting low, after following the usual horizontal parabola, took an almost vertical line of flight. Ordinary field guns are not suited to such a use, as they cannot be given the necessary inclination; the Turks had, therefore, posted their guns on the actual slope of the sand hills, burying the tail of the carriage deep in the sand to prevent the overturn of the gun owing to the recoil. This position, while it rendered a nearly vertical fire possible, made the laying of the gun very difficult. In fact, in spite of all the preparations made in advance, the aim of the gunners was wild and their fire quite innocuous. The dirigible, on the other hand, let fall other bombs, which seemed to be as effective as the first. The aeronauts, moreover, while carrying on this aerial combat, which lasted almost an hour, were able to accomplish in the most complete fashion possible the chief end of their voyage—that is to say, an exact reconnaissance of the position of the enemy's camp and estimation of the number of Turks and Arabs that had gathered in front of our lines.

"A Shadow in Court"—The Sequel

By William F. Rigge, S. J.

On February 4th of last year there appeared in this journal an article under the caption "A Shadow in Court" It instanced a case in which the liberty of an accused man hung upon the accuracy with which an astronomer could determine from the position of a shadow the exact time at which a photograph had been taken As the account was written immediately after the first trial, the subsequent history of the case is not without interest. A brief recapitulation of the facts will obviate the necessity of referring to the original number E was arraigned on the charge of having placed with malicious intent a suitcase containing dynamite upon D's porch between 2 and 3 o'clock on the afternoon of Sunday, May 22, 1910 The State produced only two witnesses, girls about 18 years of age, who stated that while walking in the neighborhood shortly before three o'clock, they saw a man answering E's description carrying such a suitcase. The attorney for the defense found upon investigation that the girls at the time were coming from a church a mile away. They had attended services there, and had posed for their photographs twice in front of the building. A prominent shadow in one of the pictures gave the attorney the idea of consulting an astronomer in the hope of finding from the position of this shadow the time at which the exposure had been made The astronomer testified that the time was within one minute of twenty-one and a half minutes after three o'clock. In that case the girls could not possibly have seen the accused at the place and time they averred. This testimony served to split the jury.

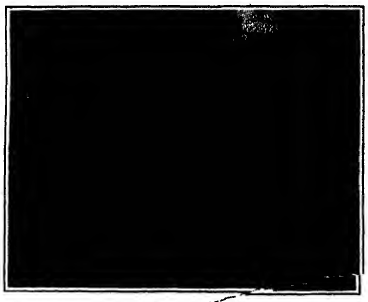
At the second trial substantially the same testimony was advanced as at the first. The attorney for the prosecution, an expert criminal lawyer, realized that his only hope of success lay in invalidating the evidence advanced in the name of science. For this purpose he belittled the calculations and predictions of scientific men generally, and by his sarcasm and witticisms kept the jury in continuous laughter The unanimous verdict of "Guilty" drew a sentence of fifteen years in the penitentiary

The defense then appealed to the Supreme Court of the State. While the sifting of the evidence was in progress, the first anniversary of the taking of the photograph occurred, and it gave the expert an opportunity of verifying his findings. The time he had assigned was in error only a quarter of a minute

Some months later the Supreme Court decided that the accused had been convicted upon insufficient evidence In preparing for a third trial the prosecution called upon G. D. Swezey, professor of astronomy at the University of Nebraska, to remeasure the position of the shadow and recompute the time. Prof Swezey, narrating the event at a public meeting of the Nebraska Academy of Science, held in Lincoln, on May 3d last, said that he studiously refrained from consulting or even referring to any of the former measurements or findings until he had completed his own calculations. The outcome was that he obtained a difference of only twenty nine seconds, thus falling decidedly within the one minute that the defense had allowed as a probable error. The State then abandoned the prosecution

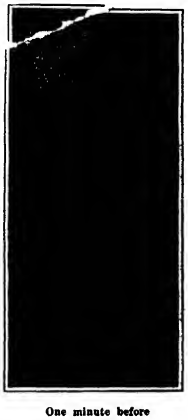
On May 22d last, the second anniversary, the shadow was again on the same spot it covered at the instant the original photograph was taken It will be there each anniversary as long as the building stands and the point that cast the shadow, as well as the wall upon which it fell, remain in their original position

Note that in the first and third pictures the left corner of the shadow is exactly in the middle of a weather board, and that it is below that spot in the second picture and as much above it in the fourth The computed time, therefore, was certainly correct to the minute, and probably so even within a few seconds.

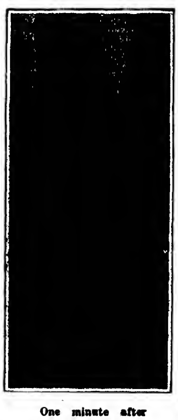


The liberty of an accused man hung upon the shadow at the right.

An astronomer testified that the picture was taken on May 22d at 3 21½



One minute before the computed time.



One minute after the computed time.

Photograph taken at 3:21½, May 22d, 1912, vindicating the astronomer.

Resuscitation from Electrical Shock

By T. Commerford Martin

Of late years, the increased knowledge of electrical phenomena and the riper experience in handling electrical energy, have done much to lessen the number of fatal accidents from electrical shock. On the other hand, the extended introduction of electricity into the arts and industries, the establishment of numerous circuits of high voltage for transmission and distribution purposes, and in general the preference given to the alternating current for a wide variety of work on account of its flexible use over large areas, have brought a much higher degree of risk than obtained under the old regime of direct current of relatively low potential. The net result has been an apparent swelling of the death roll to an abnormal extent, although in proportion to the universalized employment of electricity, the percentage of shock and fatality has doubtless fallen considerably. There are no exact statistics available on this important subject, but in view of the part that electricity plays in modern life, such data might well be increased in some of the inquiries of the United States Bureau of the Census. In 1895, when the present writer was one of its editors, the *Electrical World*, impressed with the necessity for popular instruction on the subject, issued in broad sheet form a chart of instructions to be followed in cases of apparent death from electrical shock; and a revised version of these rules was issued by the same journal in 1902. Without question, the use of these rules for securing resuscitation was successful in a great many instances; and the demand for the charts, circulated gratuitously, became so great, no one can now say how many thousands were printed. They are to this day a prominent feature on the walls of electric power plants throughout the world. It happened, however, that this chart was based on the Sylvester method, directing that the victim of the shock should be laid *on his back*, and his chest expanded and compressed by drawing his arms forward and then pushing them back against his ribs. Serious doubt arose in the course of time as to the real virtue of this method, and meanwhile the Schäfer method attracted attention as probably superior in effectiveness. It consists simply in laying the victim *on his belly*, and then applying pressure rythmically on his loins and lowest ribs. This is known as the "prone pressure" method, and it was soon taken up in Europe, although both there and here the Sylvester method persisted. A crisis was reached about three years ago, the older charts were no longer given out, and it was felt that something must be done to secure unanimity; in doing which the percentage of cases of resuscitation would obviously be raised. When the matter, or the situation, came to the notice of the National Electric Light Association, with its 1,500 private corporations engaged in public service in the United States, to the tune of 100,000 employees, $2,500,000,000 investment and 1,000,000 or more customers, it took the problem up with commendable activity, and at once organized the forces of safety. Two years ago it called into conference the leading engineering societies of the country, the United States Army and Navy, the United States Bureau of Standards, the American Museum of Safety, and the American Medical Association; and the authoritative dealing with the problem was relegated by unanimous vote to the last named powerful organization, the National Electric Light Association and the American Institute of Electrical Engineers. These three bodies selected their representatives as members of a commission, its expenses to be borne entirely by the National Electric Light Association, and then the work was taken seriously in hand. The members are as follows: Dr. W. B. Cannon, chairman, Professor of Physiology, Harvard University, Dr. George W. Crile, Professor of Surgery, Western Reserve University; Dr. Yandell Henderson, Professor of Physiology, Yale University; and Dr. S. J. Meltzer, head of the Department of Physiology and Pharmacology in the Rockefeller Institute of Medical Research—the four from the American Medical Association. Dr. E. A. Spitzka, Director and Professor of General Anatomy, Daniel Baugh Institute of Anatomy, Jefferson Medical College, and Mr. C. L. Eglin, Past-president of the National Electric Light Association—named as representatives of the National Electric Light Association. Dr. A. E. Kennelly, Professor of Electrical Engineering, Harvard University, and Dr. Elihu Thomson, Electrician, General Electric Company—nominated by the American Institute of Electrical Engineers. Mr. W. D. Weaver was elected secretary by the other members of the commission. It is quite needless to point out the distinction and capacity of this able body of men.

Three problems confronted the commission, and in reality only one of them has been disposed of thus far, in the issuance of the new rules, which are based wholly on the Schäfer prone method, approved because of its superior simplicity in application, easy performance by laymen, slight risk of injury to the subject, large ventilation of the lungs, and absence of trouble from the falling of the tongue back into the air passage. The new rules have been issued, both in broad sheet and in vest pocket form, with illustrations of the method. These are copyrighted by the National Electric Light Association to secure integrity of the rules, and are issued at cost, but on request anyone can secure permission, without charge, to reprint in any form, as the commission desires to give the rules the widest vogue and publicity. These documents were formally presented at the National Electric Light Association convention at

(Concluded on page 66.)

The Wirelessly Directed Torpedo

Some New Experiments in an Old Field

By Benjamin F. Missner

IN the year 1897, when wireless telegraphy was in its infancy, Ernest Wilson, an English scientist, was granted a patent on a system for the wireless control of dirigible self-propelled vessels. The primary object of the invention was to provide a weapon for use in naval warfare, which, if in the form of a dirigible torpedo controlled from a shore or ship wireless installation, would be most deadly in its effect on a hostile fleet. Wilson's was the pioneer patent in that branch of radio-telegraphy now commonly called radio-telautomatics. Since then a large number of patents on telautomatics have been taken out by various inventors, and several of those who have been so fortunate as to possess the means, have developed their respective systems in the effort to realize their possibilities.

Gardner of England, Wirth of Germany, Gabet of France, Roberts of Australia, and Tesla, Sims and Edison of the United States during the last ten years have attempted to solve the problem in a practical way. Gardner, Wirth, Gabet and Tesla have used their systems on boats intended primarily for torpedoes, which they control by Hertzian waves. Sims and Edison, with the co-operation of the United States Government, developed a system for controlling a dirigible torpedo through a trailing conductor, and Roberts has applied his system to dirigible balloons. These inventors have had various degrees of success in their endeavor to perfect their inventions, but apparently none has reached the goal. It is true they have controlled the movements of vessels without the aid of wires, but at the best the apparatus worked spasmodically, unsatisfactorily, and the greatest distance at which their vessels were controlled has not exceeded a half mile. But why, we may ask, have these learned men failed to secure the desired results when wireless telegraphy, the mother of radio-telautomatics, has made such wonderful progress?

By analyzing the situation we may find that early in the art potential-operated receiving devices, such as the coherer, which was developed from Branly's tube, were used, which permitted the use of recording mechanisms. As the art progressed new receptive devices were discovered which when used with the most sensitive of all electrical instruments, the telephone, proved the coherer comparatively insensitive and unreliable. Coherers and relays were discarded and replaced by the detectors and telephones, which provided a means of signaling over vastly greater distances with the same amount of transmitting power. The new detectors while forming a very desirable combination with the telephone, were entirely unsuitable for use with relays, and, therefore, those men interested in the control of mechanisms were compelled to retain the coherer as the receiving detector. This is the reason for the poor success attained in the field of radio-telautomatics. The coherer, being spasmodic ("somewhat feminine") in its action, sometimes operates when the transmitting key is pressed, and sometimes operates when no signals are sent, probably steering the boat to starboard when the signal should have sent her to port, or stopping the engine when full speed was desired.

House-boat used to demonstrate the Hammond system of torpedo control.

The coherer has, therefore, been the barrier to the realization of the invention's possibilities.

During the summer of 1911, J. H. Hammond, Jr., a young inventor of Gloucester, Mass., carried on experiments on the control of a dirigible boat, with a considerable degree of success. With no great amount of transmitting power (1.5 kilowatt) and comparatively poor antennae (80 feet and 30 feet, respectively), Mr. Hammond was able to keep the boat under perfect control at distances up to and over a mile.

John Gardner and his dirigible boat.

The boat, which has a displacement of over eight tons and a speed of about five miles per hour, was steered over a prearranged course during both day and night in all conditions of sea and weather. The course was by no means simple, following as it did circles around buoys and a complete circle around the harbor. Fishing and other vessels were continually moving about the harbor, but no great trouble was experienced in avoiding them and at the same time keeping on the prearranged course. It was found possible to steer the boat directly against either of several upright spar buoys a mile from the transmitting station. At night, lights, automatically controlled by the steering mechanisms, kept the "helmsman" at the transmitting key informed of the boat's action. The steering of the boat was accomplished by sending Hertzian wave impulses, which, affecting suitable receiving apparatus and switching devices, controlled an electric motor mechanically connected with the steering wheel. The rudder could, therefore, be made to move to port or starboard, or could be set at any intermediate position at will from the transmitting station.

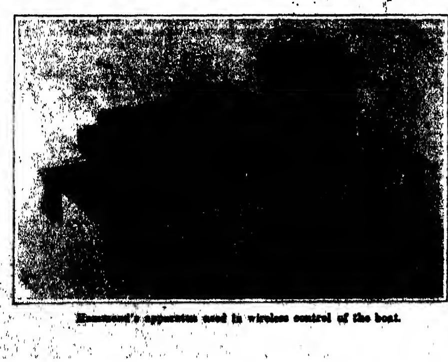
The success of Mr. Hammond's experiments is due largely to the fact that he early realized the unsuitability of the filings coherer, and adopted a more sensitive and reliable type of detector, namely, the mercury-steel disk coherer, which was invented by Sir Oliver Lodge and Dr. Muirhead, and used in their system of syntonic wireless telegraphy. While not entirely satisfactory, the Lodge-Muirhead coherer proved a great advance over the filings coherer, and no difficulty was experienced in operating the sensitive relay used with it at distances up to two miles.

Mr. Hammond, encouraged by last year's work, is building and equipping a large station at Gloucester for further experiments in telautomatics, and with non-interferable systems. Two towers 340 feet high for supporting the aerial wires are being constructed, and eight complete transmitting and five complete receiving sets will be available for use in experimental radio-telegraphy and telephony.

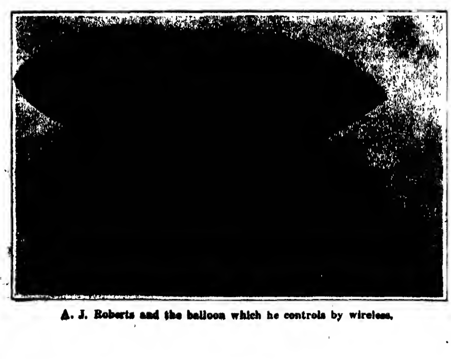
An entirely new receiving detector and a sensitive relay have been developed during the past winter which will greatly increase the range of operation. These instruments, being electrically and mechanically stable, will require no adjustment.

In addition to the wireless equipment, a boat of special design is being built, which will travel at a rate of thirty miles per hour. This boat will be equipped with the wireless control apparatus and will be operated from the station. A 24-inch searchlight and selenium cells of extreme sensitiveness will also be used in controlling the boat, by sending light wave impulses, the wave length of which is of the order of 1/44,000 of an inch in length, instead of or in conjunction with impulses of electro-magnetic waves whose length is of the order of 3,000 feet.

Considering the amount of work that is being done along the lines of torpedo control in the United States and in Europe, and the progress that is being made in radio-telautomatics, it is very probable that the dirigible torpedo will, within a few years, occupy a prominent place as a deadly weapon in naval warfare. It would be absolutely invisible except in the very rare case of an absolutely calm sea.



Hammond's apparatus used in wireless control of the boat.



A. J. Roberts and the balloon which he controls by wireless.

The Business Side of German Science—VIII

Making Money With the Aid of Technically Trained Men

By Waldemar Kaempffert

(Concluded from page 96, July 19th, 1919)

[THIS is the eighth of a series of articles, written by the Managing Editor of the SCIENTIFIC AMERICAN, *on German industrial conditions. The author was sent abroad by the publishers for the express purpose of gathering the material on which the articles are based. In this and the article to follow, the part played by the technically trained man in German business is pictured.*

The amazing industrial development of modern Germany is to be attributed in large part to technical education and to the application of science to business. Capital and science work hand in hand. Every one of the great chemical discoveries of our times, most of them made in Germany, are the result not of haphazard experimenting, but of systematic research that has meant the expenditure of princely sums. All German manufacturing is so thoroughly saturated with science, that even the small producer practises on a miniature scale the methods of his larger rivals.]

The Story of Indigo.

The pertinacity with which a German chemical company will carry on investigations for years, fully convinced that ultimately the goal will be reached, finds no more brilliant example than the development of a commercial process for the manufacture of artificial indigo. In the eighties Prof. von Baeyer of Munich succeeded in producing synthetic indigo—a great achievement. Two of the most powerful chemical firms of the day took up the invention almost immediately. They set chemists and engineers at work. After much time, money, labor and thought had been spent in endeavoring to base an industry on von Baeyer's discovery, it was found impossible to produce indigo in commercial quantities by the means that he had indicated. The firms who backed the invention were discouraged perhaps, but not beaten. When Heumann discovered a method of obtaining synthetic indigo from the phenylglycins, a commercial future for artificial indigo seemed to have dawned. Heumann was practically taken into partnership with capitalists who recognized the immense possibilities that lay in his discovery. Without them he would have been able to do nothing. Seven years of hard work elapsed before the first indigo could be manufactured by Heumann's process for the market.

It pays to spend money and time so lavishly. The amount of indigo manufactured to-day would require the cultivation on an area of more than one-quarter of a million of acres of land in the home of the indigo plant. As late as 1897 thirteen million pounds of indigo were grown, valued at twenty million dollars. Not more than one-sixth of this quantity of natural indigo is now marketed. The Calcutta harvest for example, in 1896 amounted to 158,922 maunds and in 1909 to only 81,200 maunds, a maund being 82.14 pounds. In Java, in 1898, there were 122 indigo plantations; in a few years they were reduced to 28. A harvest which in Java amounted to 12,580 boxes in 1898 was reduced to 2,015 in 1908. In 1897 Germany imported $3,200,000 worth of natural indigo, in 1909 only $160,000 worth. On the other hand the export of synthetic indigo in Germany amounted to nearly $2,000,000.

The same story is repeated in the history of alizarin. In 1868 France exported about $600,000 worth of madder. To-day madder is almost unused. Instead, millions of pounds of artificial alizarin are manufactured, seven-eighths of the entire output in Germany. In 1892, 320,000 pounds of cochineal were used in Germany. In 1897 the use of cochineal had dropped to about 34,000 pounds.

Reducing the Cost of Old Processes.

The men in the research laboratories of German manufacturing companies are concerned not only with the discovery of new compounds and the inventing of new apparatus, but also with the simplification and the cheapening of old and long established processes. There has been a vast improvement, for example, in the manufacture of salicylic acid, of which one hundred and twenty-nine tons were exported from the German Empire in 1882, and five hundred and two tons in 1905. Although in twenty years the amount exported increased four times, the price of the acid dropped to one-sixth of what it was originally. In 1900, again, anti-febrin was worth about seven and one-half times what it brought in 1905. Vanillin, which has taken the place of vanilla extract, and which has been produced artificially for the last thirty years, was worth about $1,800 a pound in 1876; in 1902 it was worth about $8 a pound. These remarkable reductions in the selling price are to be attributed entirely to simplified methods of manufacture. The result of the cheapening has been the opening of a much larger market than could otherwise be supplied.

In the dyestuff industry the advances which have been made in the last decade in thus improving original processes is perhaps more marked than in any other phase of German manufacturing. Most of the improvements have resulted in securing a greater degree of fastness to washing, light and similar agencies. Thus, in dyeing cotton the want of fastness of the earlier "salt" dyestuffs soon led to attempts to fix the colors after dyeing. One result of these many attempts was the introduction in 1894 of Vidal black. Immediately a wonderful development of "sulphide" dyestuffs followed. The cotton dyer obtained cheap dyes of much greater fastness than those of the old "salt" class, which, therefore, were gradually displaced. Sooner or later the sulphide dyestuffs will have to give way to the newer vat dyes of the anthracene and indigoid classes when they have been cheapened sufficiently.

Sometimes the discovery of a new process may lead a rival manufacturer to begin a systematic study of an old process in order to improve and cheapen it to such an extent that it will not be crowded out of existence. An example is to be found in the making of sulphuric acid. When the Badische Company devised a method of making sulphuric acid commercially by the contact process it seemed as if the old lead-chamber was doomed. But the story of the competition between the electric light and the gas light was repeated; a method was found of improving the old lead-chamber process and increasing its efficiency, so that it is still worked side by side with the contact process.

Testing New Products Before Marketing Them.

The introduction of a new dye, a new drug, a new explosive, and new fabric is not conducted in a haphazard way. Business men the world over realize that there is an ethical side to the selling of goods. The old days when a salesman was simply a hired liar who stopped at nothing in selling his goods are over. A modern manufacturer not only refuses to misrepresent his products, but he will not even market them if they are not at least as good as the old.

In connection with every research department in Germany will be found a testing laboratory—a place where a newly discovered product must prove its worth. A new dyestuff is subjected to hundreds of practical tests before the public ever hears of it. It is tested for fastness by exposing it to the sunlight by ascertaining how it withstands ordinary alkalis and much washing, and by noting its effect on leather, paper and fabrics in general. As a result of hundreds of tests it may be revealed that a new chemical product is not as good as an old one, or that it is injurious in some way. Despite the fortune that may have been spent in devising a process for its manufacture, it is cast aside immediately.

The introduction of new drugs and medicaments imposes this moral obligation to a high degree. At Hoechst will be found perhaps the largest works in the world for the production of medicines and chemicals that are used in the ordinary physician's practice. Here will be found remarkable laboratories for testing the qualifications of a new virus, serum, drug, or narcotic which is to be used in curing human ills. The laboratory physician works hand in hand with the chemist; the physiologist with the physicist. No bacteriological laboratory, no hospital is conducted with more scrupulous care. A fine stud of thoroughbred horses, from three to eight years old, are an indispensable aid in supplying sera and anti-toxins. The therapeutic agents discovered are rigidly controlled partly in the Institute for Experimental Therapeutics of Frankfurt, partly at Hoechst itself. Diphtheria serum, anti-dysentery serum, anti-pneumococci serum, anti-streptococci serum, scarlet streptococci serum, tetanus serum, Robert Koch's tuberculin preparation, as well as Ehrich's salvarsan are here prepared and carefully tested before they are sent out.

Analysis of Raw Material.

No longer is raw material bought simply by quantity and with only the most superficial regard for quality. Mass production is the reason. When the output of a steel mill or a sugar factory is millions of tons a year, it pays to save a cent a ton on raw material; it pays to determine beforehand and exactly how much of the raw material can be utilized to produce a certain amount of goods. The old-fashioned miller for example used to thrust his hands into the grain that he bought in order to feel its moisture; or he would grind it between his teeth. It is perfectly obvious that by such crude methods he could not determine differences in moisture of one or two per cent; yet such extremely slight differences may be of untold importance in modern milling. Grain is sold by weight. If it contains a large percentage of water, the miller is simply buying moisture which easily evaporates. Hence, we find that the modern miller—and particularly the modern German miller—scientifically analyzes the grain that is offered to him. Not only does that analysis govern the price to be paid for the grain, but it determines its keeping qualities. When grain is to be stored for a long time, it is not a matter of indifference whether it contains fourteen per cent or sixteen per cent of water. Experience has shown that wheat containing as much as fifteen per cent will keep for a long time, whereas wheat containing only sixteen per cent—only one per cent more—may suffer.

Only a very wealthy firm, it may be argued, can afford to pay a scientifically trained man to test raw materials in this way. That is true enough. But the small firm in Germany proceeds scientifically nevertheless. Much valuable technical assistance is given by manufacturing firms to small consumers of their products who are not able to engage a chemist or a technically trained man regularly. Thus the firm of Simon, Bühler und Baumann of Frankfurt employs a chemist whose chief duty it is to assist breweries and millers to reduce their cost of manufacture by analyzing raw material and waste products, and submitting the results of his examination. Moreover, there are dozens of consulting technologists whose services may be engaged for no very large sum.

The Sociological Side of German Industry.

There is a sociological aspect to German industrial science which is obscured by a national prosperity expressed in exports that amount to millions and millions of marks a year. Each new coal tar drug that is unearthed, each new method that is discovered for the utilization of waste material, means work. It is no small task to provide places for one-third of a million human beings, who annually demand a chance to earn their living. The fact that there is so little poverty in Germany, that a task is provided for every able-bodied man, is due in large measure to the laboratory scientists in the employ of the huge manufacturing companies.

Macquarie Island

PUBLIC attention has recently been directed to Macquarie Island, owing to the fact that the Mawson Antarctic expedition, on its way south, established a wireless telegraph station here, so that the island is now in daily communication with Hobart, Tasmania. It was hoped that this station would be able to relay messages to a wireless station at Adelie Land, the base of the expedition on the Antarctic continent, but this plan has proved impracticable. It is said that magnetic disturbances due to the proximity of the south magnetic pole make communication between these two points impossible. However, the Macquarie Island station has proved of some value to shipping in Australian waters by giving timely notice of storms coming up from the south.

Macquarie Island, which belongs to Tasmania, is about 750 miles southeast of Hobart, and is, therefore, a halfway point for expeditions proceeding to the Antarctic on the Australian side. It was visited by the expeditions of Scott and Shackleton, as well as by Dr. Mawson's party. The island is about 22 miles long by 5 broad, and has a rugged coastline, rising sheer out of the water to a height of 1,500 feet in places.

According to a recent consular report this island has been leased by the Tasmanian government to Mr. Joseph Hatch, who has established here the lucrative business of catching penguins for their oil; probably the most southerly industry of the world, except certain fisheries. It is said that there are 80,000,000 penguins on the island. The oil is obtained by boiling the carcasses in digesters capable of dealing with 800 birds at a time. The product is barreled and sold to binder-twine makers in Australia and New Zealand. The chief obstacle to the success of this enterprise is the fact that the island has no harbor. Vessels have to lie about half a mile offshore, and all material is conveyed to and fro on rafts made of casks. Several ships have been wrecked in attempting to visit the island.

Stress in Aeroplanes

To the Editor of the SCIENTIFIC AMERICAN:

Apropos of your recent editorial on the stress in aeroplanes, I note that the values in my table in the SCIENTIFIC AMERICAN of August 26th, 1911, have to be multiplied by 22/15 to make them correct. The abstract formula used in computing those values is right, but by an oversight the factor 22/15 was omitted from the arithmetical computation. All the more, therefore, the warning in your editorial appears to be well founded.

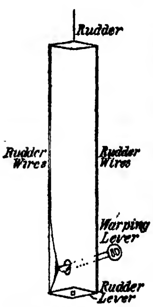
An Explanation of the Quimby Accident

To the Editor of the SCIENTIFIC AMERICAN:

As manager of the aviation meeting at which Mr. Willard and Miss Quimby came to a violent end, I had unusual facilities for making prompt examination of the wreckage and I wish to make the following report in the hope that all monoplane constructors will avoid such a defect in construction as existed in Miss Quimby's Blériot monoplane.

Referring to the rough sketch which I inclose, which is a plan view of the machine upside down as it rested in the water, I found that one of the two left-hand control wires (all of the Blériot control wires are in duplicate) had caught over the lower end of the warping lever. Of course this is a defect in construction as the rudder wires should either have been put farther away from this warping lever, or else been run through guides at this point so as to prevent them becoming entangled with it.



Plan view—upside down.

The reason this has not happened before in a Blériot monoplane is because the warping lever, as used in Miss Quimby's machine, was not the conventional Bleriot "cloche" which was a feature of my 70 horse-power monoplane, and all others I have ever seen. I noticed this departure from conventional Blériot practise when I examined Miss Quimby's machine before the flight. I have also called the matter to Monsieur Blériot's attention in a letter under this date.

It is some satisfaction to know definitely the cause of this accident and I assure you that I hardly think there is a chance of my being mistaken. I was the first one to examine the wreck and this rudder wire was caught over the control lever when I looked at the machine. And from what happened in the air, for I saw the whole accident, I am convinced that this was the difficulty. At any rate, the construction should not have been such that this wire could possibly have been looped over the control lever whether in the air or at any other time. It is too bad that all aeroplane accidents do not leave such a clear record of their cause.

EARLE L. OVINGTON.

Newton Highlands, Mass.

[We have had an interview with Miss Quimby's mechanic, and the following is his version of the accident:

Miss Quimby had returned from her flight to the Boston Light and had made one big circle over the field, at a speed of 70 to 80 miles an hour. She was flying without banking the machine, which was unnecessary on account of the size of the circle she was describing. At the beginning of the second round the mechanic saw Mr. Willard fall out. Relieved of his weight, the machine instantly dived at an angle of about 60 degrees. Miss Quimby succeeded in partially righting it before she, too, was flung out. The machine glided down at an angle of not more than 30 degrees, struck the water, and turned over. The mechanic examined the wreck of the machine almost immediately, and found everything intact about the controls. He states that there was no fouling of the rudder wires by the control post, that, indeed, this was an impossibility because there was a clearance of at least four inches between the end of the post and the rudder wires when the post was moved as far as possible to the right or to the left. It is difficult to reconcile the mechanic's explanation with that of Mr. Ovington. Hence, we publish both accounts, suggesting that the true cause of the accident will probably never be known. The mechanic's explanation of how the accident happened starts with the loss of the passenger, who, he believes, may have become ill and have stood up in an endeavor to signal to Miss Quimby to descend. It is possible that the machine was skidding sideways slightly and that Willard fell over the side. The mechanic did not see just how he fell, but saw everything that happened afterward. Miss Quimby's arms were broken and her chest crushed in, evidently from her being thrown forward with great violence on the curved hood when the machine made a sudden dive. Consequently, she could not right the machine, even if it were possible when once the passenger was gone. Miss Quimby had never experienced any difficulty in controlling her powerful Blériot. That she could manage it perfectly was shown by the fact that she alighted and started on a strip of ground only 100 feet wide during her flights at Boston. From all this it would appear that the machine had a fatal defect in becoming unbalanced as soon as the passenger was thrown out. Without a passenger or pilot, however, it seems to have been perfectly balanced and to have glided safely to earth.—EDITOR.]

Mississippi River Levees

To the Editor of the SCIENTIFIC AMERICAN:

The levees or dikes of the Mississippi River continue giving way, thus proving by practical demonstration the futility of the earthen dike system now in vogue along its banks for protection against overflow. The Government as well as individuals has sustained irreparable loss this season from the innumerable crevasses caused by the record-breaking flood height. It would be a conservative estimate to place the value of the standing levees along the Mississippi at $50,000,000. This is for levees now standing that have successfully weathered this season's flood, it would not include millions of dollars spent in years gone by for levees washed away, fallen in, etc.

There is now a strong movement on foot by the different States, petitioning Congress to take over to Government care the building and maintenance of these dikes. No doubt Congress will do the right thing particularly as it is in line with the administration policy.

By way of economy to conserve the fifty million dollars of dikes now standing, it would not be a bad idea to sheet pile directly through the center of the crown. Tongue and groove piling such as "Sewall" or "Wakefield" would answer admirably, particularly if the timber was creosoted, thus insuring an unlimited life; this would present a powerful barrier and be absolute proof against the ravages of musk-rats, cray-fish and king-fishers. The piles should extend from the top of the levee down into the original ground fully 10 feet. In localities where cypress timber is obtainable, the piles could be made of that wood which would last indefinitely underground, without treatment, and be a saving of nearly 50 per cent over creosoted timber. This work, using cypress, ought not to cost more than $5 per foot, in place.

New Orleans, La. C. JULIAN BARTLETT, C. E.

Successive Passages of the Sun Through the Equinox

To the Editor of the SCIENTIFIC AMERICAN:

To the inquiry of Mr. John Ford, appearing in your issue of May 25th, I have to say that in the issue of March 2nd, the interval between successive passages of the sun through the equinox (365 days, 5 hours, 48 minutes, and 46 seconds, according to Mr. Fox) is given as 365 days, 5 hours, and 49 minutes, and that my figuring was done accordingly, but I failed to take into consideration that a leap year is added every 400 years. Further, in figuring out the editor's answer, I discovered that my statement, "at the end of each century we are still short 344 minutes," should have been 384 *minutes* (1,440 less 1,056) an error which was probably overlooked both by the editor and Mr. Ford.

After going over Mr. Ford's figures I find them correct, and thank him for having called my attention to the subject.

WILLIAM FALBE.

Mayaguez, Porto Rico.

A Card Trick

To the Editor of the SCIENTIFIC AMERICAN:

The following card trick was explained to me during a recent railroad journey, and I was told that so far as the party knew, it had not been published. It is called the "Hawaiian Islands," and the little story was told as the cards were laid out in playing the trick. The story ran something like this:

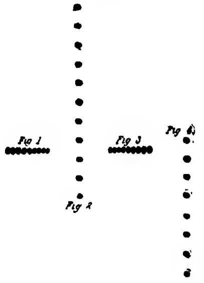
There were four islands in the sea (and the four aces were laid out for the islands) and on these islands there were diamonds (four diamonds being placed one on each ace) and four kings went to get the diamonds on these islands (putting the four kings on the four diamonds) and these kings had nothing to dig with but spades (four spades being laid out, one on each pile) and four pirates went to rob the kings of the diamonds (the four jacks being laid out on the piles) and these pirates had no weapons but clubs (four clubs being placed out on the piles) and four queens went to save their kings from the pirates (the four queens being placed one on each pile) and these four queens had nothing to take with them but their hearts (four hearts being laid one on each pile). When the cards are so laid out we have four piles beginning with an ace below and including each an ace, a diamond, a king, a spade, a jack, a club, a queen, and a heart. Now place these four piles one upon another into a single pile or pack. This pack may now be cut, by a square cut, no double cuts allowed, and it may be cut as many times as desired by the party to whom the trick is being exhibited. Then after the party has cut as many times as desired, take the pack and put the cards out in eight piles, taking them in order and going back to the first pile from the end of the eight in regular order through the eight piles, and it will be found that all four aces will be in one of the eight piles, all four kings in another, all four queens in another, and so on throughout the series of eight. It may add to the interest of the trick for the party playing it to insist on the right of making at least two cuts after the other party has cut to his heart's desire. The trick is absolutely certain in its results when properly played, and it makes no difference whether the party cuts once or a thousand times, if the cut is always a square cut. He may cut deep or shallow as he pleases, and the result is not changed.

REGULAR READER.

Where Do the Secondary Images Come From?

To the Editor of the SCIENTIFIC AMERICAN:

I have observed that when light from a bright source, for example, an electric light, falls on a plate glass mirror at a very large angle of incidence—as near as possible to 90 degrees—a number of images become visible in the mirror. At first I supposed this was due to multiple



Variations produced by rotating the glass.

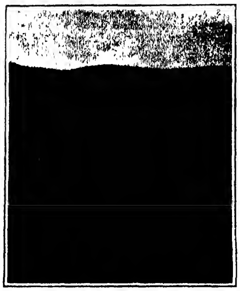
reflection from the two faces of the glass, but I have difficulty in accounting for the different positions of the images. If the glass is kept in the same position but rotated about an axis perpendicular to the plane of the mirror, the brightest image, which is the second one in the series if a silvered mirror is used, seems to remain in about the same position, but the secondary images move around the bright one.

When the glass is held in one position, the images appear as in Fig. 1. When the glass is rotated through 90 degrees, the images move to the positions shown in Fig. 2. Another 90 degree rotation gives Fig. 3, and so on. In Figs. 2 and 4 the secondary images appear to be about as far from the eye as the primary, but in Figs. 1 and 3 I believe they are unequally distant from the eye, although it was very difficult for me to determine whether the primary or secondary images were the nearer. I thought that perhaps in Fig. 1 the secondary images were nearer and in Fig. 3 they were farther from the eye than the primary, or *vice versa*. If this is true, it would indicate that the secondary images were rotating in a circle or ellipse the plane of which is nearly perpendicular to the plane of the mirror but oblique to the reflected ray along which, of course, the eye is looking.

The light giving the secondary images after the first three or four is plane polarized, as was shown by examining it with a Nicol prism. I suppose this might be accounted for by the several reflections which it has undergone, but why should the secondary images change their location while the mirror merely rotates in its own plane?

It occurred to me that the glass might be double refracting and the secondary images due to the extraordinary ray, but this does not seem very clear to me. If this is the true explanation, the question at once comes up as to what becomes of the ordinary ray. The plane of polarization does not rotate as the secondary images move around the primary.

Emporia, Kans. W. B. LEWIS.



The ruins of Samaria, looking west.

Recent Excavations at Samaria

Discovery of the Palace of Ahab

Herod's Buildings Unearthed and Ancient Jewish Inscriptions Found

By Harold J. Shepstone

Idols from Samaria.

ONE of the most interesting and valuable discoveries so far recorded in the field of Biblical archæology has been the recent unearthing at Samaria, in Northern Palestine, of the palace of a Hebrew king, believed to be the "ivory house" of Ahab. Labels with Hebrew writing, which seem to have been in actual use during the life time and perhaps in the households of Omri and Ahab, have also been found, as well as many fragments of pottery. Many Biblical names appear in the writings, such as Elisha, Asa, Nathan, Uzza, Sheba, and Abiezer.

Samaria was the ancient capital of the Northern Kingdom of Israel. When Solomon died, about 930 B.C., his kingdom broke into its two natural hereditary divisions, Israel and Judah. Shechem, the first capital of Israel, lying in a narrow valley and therefore difficult to defend, was abandoned for Tirzah. This in its turn, about 875, was given up for a new site. Omri, founder of the third dynasty of Israel, chose for his capital an isolated hill some six miles northwest of Shechem. The city which he built here he called Shomeron, now best known by the later Greek form of the name, Samaria.

The hill rises to a height of 400 to 500 feet above the valleys which surround it. From the summit, some 1,400 feet above sea-level, one may see the Mediterranean, on clear days, some twenty miles to the west. There are also fine views into higher mountains on the north and east, and over the hills and valleys south and west. The naturally steep sides of the hill were easily rendered impregnable by massive walls. The Herodian city, occupying the top of the hill, was about two and a quarter miles in circumference, and the city of Omri was perhaps not much smaller. The Herodian wall can still be easily traced. There is no fountain on the hill, and the people of the city must have been dependent on a spring across the valley and on rainwater stored in cisterns, of which a great many have been recently unearthed. The hill and the country around are fertile, producing good crops of olives and figs, grain and onions, and in antiquity, grapes also. For agricultural purposes the hill and those about it have been heavily terraced, a work which has greatly disturbed and confused the ancient débris.

Samaria remained the capital of Israel till taken by the Assyrians in 722. Here Ahab, under Jezebel's influence, built a temple to Baal, later destroyed by Jehu, and here it seems he built also his "ivory house" or palace, described in the First Book of Kings. Then it was in Samaria that Elisha had his home. The city underwent many vicissitudes while under Assyrian and Babylonian rule. It reached its highest artistic glory, however, under Herod the Great, who rebuilt it in great splendor and named it Sebaste or Sebustyeh (Latin, Augusta) in honor of his imperial patron, Augustus. Sebustyeh is still the name of the village on the eastern slope of the hill. Herod fortified the place, and built a great temple here in honor of Augustus.

This, briefly, is the history of the site of the recent excavations which have been most fruitful of result. They were undertaken by the Harvard University. The only condition which the Turkish Government insisted upon was that the place be left just as it was before the excavations. This compelled the explorers to do their digging in sections, the earth from each fresh section uncovered being used to bury again that already laid bare after it was minutely examined and fully and accurately planned. Hence it follows that of the very extensive work of uncovering done, first under the direction of Prof. Lyon of Harvard, and later under that of Dr. Reisner, well known in connection with similar work in Egypt, only comparatively limited portions can now be shown by photographs.

The most extensive and the most interesting work done was that on the summit of the hill. Here sometimes as many as four hundred men, women and boys, including gangs of experienced workers from Egypt, were employed at one time, and here, by long continued and indefatigable toil, the rubbish of successive generations, civilizations and conquests was removed, for a depth of many feet, until the bed rock was reached, which disclosed, almost without a doubt, the extensive palace of Omri and Ahab, covering an area of nearly two acres. The lower courses of the masonry which came in contact with the rock showed the same peculiarity as was discovered when, nearly a generation ago, the wall of the Temple inclosure in Jerusalem was laid bare to its foundations, eighty feet below the present surface. The first course of stone in the temple was embedded in the living rock, in such a way that that layer had rock on all three sides of it, which seems a distinctively Jewish feature. It was at this level in the excavations at Samaria that an alabaster vase, with the Egyptian inscription of their contemporary king, Osorkon II., was found, confirming the assumption that this was the palace of the Jewish kings.

Here it may be noted that this is the first and only palace of a Hebrew king ever found, and accordingly is unique and of the deepest interest to archæologists and Biblical scholars. It was undoubtedly an immense building, consisting of chambers grouped around courts. Here and there stand portions of the finished wall to a height of several courses of stone. Moreover, two grades of construction appear, a coarser and a finer. The explorers suggest that we have here the palace of Omri enlarged in a superior style by his son Ahab.

There were also discovered here some seventy-five fragments of pottery inscribed with records or memoranda in the ancient Hebrew script. This is not the comparatively modern square Hebrew character with which most persons are familiar, but that ancient writing, closely allied to the Phoenician, which is found on the Moabite Stone and the Siloam Tunnel Inscription. The character of these inscriptions has settled one disputed point about that of the Siloam. It shows that it could easily have been written in the time of Hezekiah, as it purports to be, for here is writing of the same type used at Samaria more than a century and a half earlier, for Ahab lived in 896 B. C. and Hezekiah in 727. These inscriptions are written in ink with a reed pen, in a flowing hand, proving that this was the common form of writing at that period. The words are evenly divided from one another by dots or strokes, making it much easier to decipher them. It is evident that the inscriptions were written upon jars of wine and oil, and even a date is added, evidently the year of the king's reign. The owner's name is given, as well as the person or place whence the oil or wine came.

Here are some of the inscriptions, proving how exact the ancient scribes were in their methods:

"In the tenth year. For (or belonging to) Shemaryo. From the Tell. A jar of fine oil.

"In the ninth year. From Shaphtan. For Ba'alzamar. A jar of old wine.

"In the eleventh year. From Shemida For Heles, Aphsah, Baala (and) Zeker.

"In the tenth year. Wine of the vineyard of the Tell With a jar of fine oil."

These jars were evidently stored for their owners, but where no owner is mentioned the wine probably belongs to the king's palace. It will be noticed that in some of the inscriptions the "Tell" or "Vineyard of the Tell" is mentioned. It is evident that this vineyard must have been one that was especially well known. No vineyard in all history was so well known as the "Vineyard of Naboth," and it gained its fame in the reign of King Ahab.

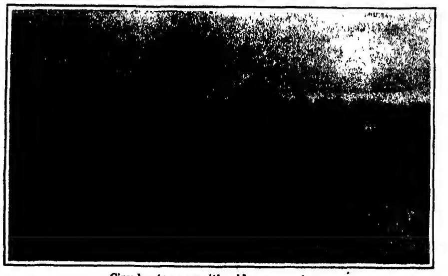
The excavations on the summit showed four superimposed eras of structures—Jewish, Babylonian, Greek, and Herodian or Roman—in one case, as it were, preserving within the inclosure of the larger building of later date the core of the older edifices. Of the Roman remains found the most imposing was the 80-foot wide staircase leading down to an altar and probable temple, put up in honor of the Emperor Augustus, where was also found the huge marble trunk of a Roman statue, lying headless and without arms or limbs, which was in all probability that of Cæsar. The crate containing this relic can be seen in one of our photographs at the foot of the great staircase

Besides the remains just mentioned found on the summit of the hill there was uncovered on the east side of the hill, near the native village of Sebustyeh, the large Roman basilica, the largest and most perfect of the buildings unearthed here, with its tribune, in semicircular form, still intact, into which later Arab masonry was fitted, and below which earlier remains of places of worship could be inspected. Some work was also done in the triple colonnade, scores of whose monolith columns are seen, some erect and some prone, and all without their capitals, along the brow of the hill, which colonnade led from the tower-flanked western gate of the city to the forum and basilica on the east. Beside this the city wall was traced all round the hill, showing that it was a larger city than the present Jerusalem within the walls.

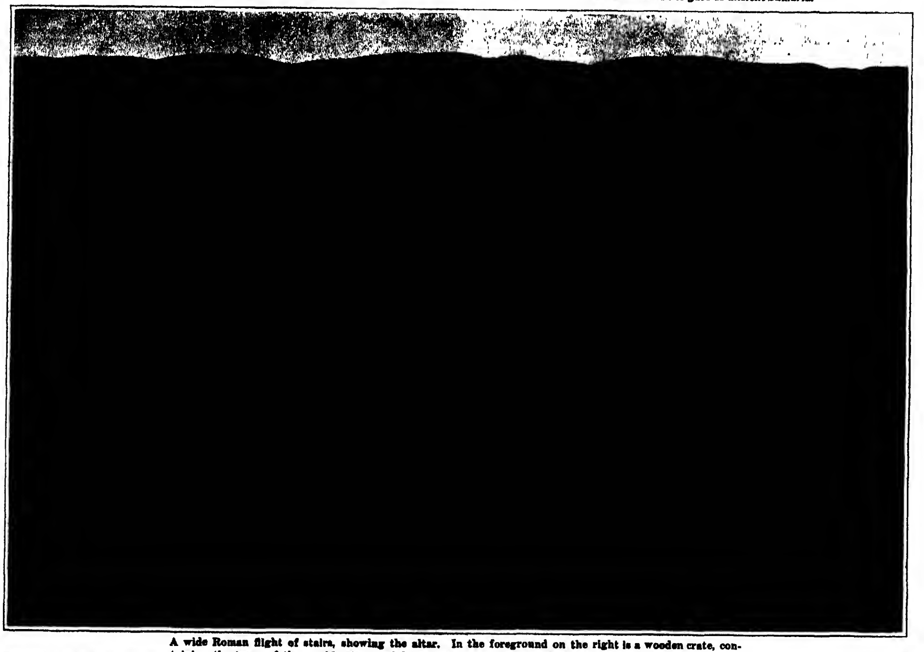
The work around the city gate on the west proved particularly interesting, for this gate has generally been connected with the story of the lepers at the time of the three years' siege by the Syrians, who, on going to the camp of the enemy rather than starve before the city gate, found it deserted, and bringing the news to the famished inhabitants, brought about the fulfilment of the saying of the man of God that on the morrow a measure of fine flour should be sold for a shekel and two measures of barley for a shekel, and that though the disbelieving officer of the king should see it, yet should he not taste of it, it transpiring that he was trodden under the feet of the eager and hungry citizens surging through the gate. Here Roman, Greek and Hebrew remains were found superimposed one on the other, betraying, among much else, this peculiarity, that whereas the towers were constructed so that they led east by north to the royal palace, yet when the Romans reared their magnificent colonnade, the angle of the gate was altered, being turned to the south so as to lead through their new covered street, lined with stately columns, to the Roman tribunal.

It is Dr. Reisner's intention to resume the work of excavation during the coming summer. Only a small portion of the mound has so far been explored. It is thought by many that here may be hidden valuable documents telling of the life and history of the early Jewish kings. Then it must not be forgotten that the age of Ahab is only a century away from that of David. The division of the land of Palestine into two kingdoms—one with Jerusalem as the capital and the other with Samaria as the capital—occurred only fifty-six years before the time of Ahab. Solomon and all his glories were still fresh in the memory of those still alive, and any part of the literature of this important period may be discovered when the rest of the mound of Samaria is excavated. That there are certainly some documents on clay, if not on papyrus, is indicated by the finding of a piece of the clay envelope of an Assyrian letter, with a part of the name of the man to whom it was addressed still there. The finding of even a fragment like this indicates the great probability that in the mound may be a great mass of these letters, in fact, all the records of the Northern Kingdom of Israel, for the Assyrian language was used at that time in correspondence between Palestine and Egypt, as has been proved by the Tel-el-Amarna letters discovered in Egypt a few years ago. Such letters would parallel the Biblical narrative.

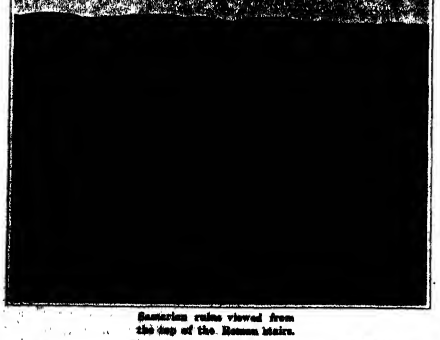
Row of ancient columns of the Herodian colonnade among the ruins of Samaria.



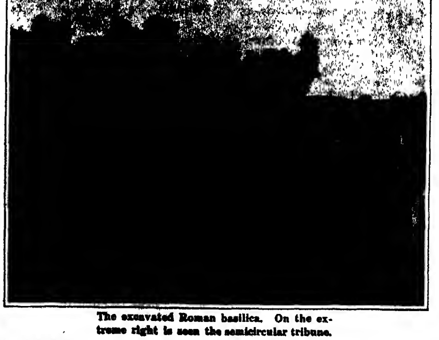
Circular towers, with older square base, which flanked the gate of ancient Samaria.



A wide Roman flight of stairs, showing the altar. In the foreground on the right is a wooden crate, containing the torso of the marble statue of Cæsar which was found in the early stages of the excavations.



Samarian ruins viewed from the top of the Roman stairs.



The excavated Roman basilica. On the extreme right is seen the semicircular tribune.

RECENT EXCAVATIONS AT SAMARIA

Handcuff Releases Under Difficulties

The Remarkable Feats of Harry Houdini

AMONG the well known vaudeville entertainers must be mentioned Mr Harry Houdini whose celebrated feats with handcuffs strait jackets and various restraints used to confine the insane and criminals are well known The public always seems to be interested in seeing the other fellow get away from a tight place so that it is little wonder that Houdini's audiences are always large Our attention has recently been attracted to a number of feats which he has been performing in New York and other cities the culmination of which perhaps is the aquatic box trick which we will now describe

On Sunday July 7th Mr Houdini invited a party of newspaper men and those interested in magic to witness a very remarkable box trick on New York Bay This event was scheduled to take place at a pier on the East River but owing to police interference the scene of operations was transferred to the deck of a large lighter which was towed to the dock of the Quartermaster's Department at Governor's Island As this was Federal property the police could not interfere with this act

A large wooden box 40 inches long 22 inches wide and 24 inches high was provided This box was carefully examined and no indication of panels bolts or springs was detected After divesting himself of his outer clothing and after a committee had seen that he did not have any concealed keys or devices for picking the locks of the handcuffs he submitted cheerfully to be manacled with leg irons two pairs of handcuffs and elbow irons Any of the spectators had the privilege of bringing their own handcuffs if they so desired as Houdini does not care about furnishing articles of this kind when he is making his more important tests The cover of the box was removed and Houdini crouched in it in a stooped position somewhat resembling the doubling up of a jack knife The cover was then nailed in place with thirty six wire nails and the entire box was banded with band iron or as it is technically known packed for export On each side a length of iron sewer pipe was secured and iron sash weights were introduced into the pipe thus affording a convenient method of weighing down the box so as to cause it to sink to the level of the water Two hundred pounds of iron was used Holes had been bored in it to permit the entrance of the water so that the box itself could be readily submerged The box was then carefully roped so that no escape from it could have been possible had the nails and band irons been non-existent or have given away Some of the planks from the lighter were removed and the box was shoved out on them and was finally dumped in the water In exactly a minute and ten seconds Houdini emerged from the water swimming toward the lifeboat which had been provided The act was witnessed by thousands of spectators who crowded the decks of three ferryboats The box was hauled onto the deck with the aid of one of the spars of the lighter and the box was carefully examined Nothing was found in it except the useless manacles which had failed to bind Houdini under the most adverse conditions Considering the danger of this feat and the entire absence of any paraphernalia such as traps etc it appears to be all the more wonderful This may be regarded as one of the most remarkable tricks ever performed and it is only regrettable that a feat of this magnitude cannot be tried before a larger gathering of spectators

Houdini's box tricks, his milk can trick and similar entertaining feats will not appeal to the average person as much as his bridge dives which have taken place in all parts of the world. We are able to show two or three photographs which give an adequate idea of the remarkable nature of a feat of this kind. In one of the engravings we see Houdini with his hands manacled behind his back and his arms also confined by elbow irons. This photograph was taken just before an 80-foot jump at Sydney, Australia. The next photograph shows the agonized face of Houdini after he struck the water at the wrong angle. Blood flowed from his nose and mouth. This goes to show that the career of the professional strong man, jail breaker and handcuff king has not been altogether unfraught with danger Several of his imitators have tried similar feats with disastrous results, such as broken ribs, and even two of them paid the penalty with their lives, being drowned with the manacles still on their wrists Owing to the uncertainty of an act of this kind if unsuccessful it would be almost impossible to rescue and resuscitate a person before he is drowned.

A third photograph shows the position of Houdini's body in his famous jump from the Queen's Bridge, Melbourne, Australia, in March, 1910 His hands were heavily ironed behind his back with handcuffs and he succeeded in reaching the surface in a surprisingly short space of time In this case he was under water about two minutes. A gruesome incident occurred at the time of this dive The shock of Mr Houdini striking the water was great enough to bring to the surface the body of a man who had been drowned some days before, thus naturally adding greatly to the excitement.

We do not pretend to give any explanation of Houdini's performances We can only say that he states that most of the public *exposés* of tricks of this kind are absolutely worthless, as they would not work in practice under the severe conditions of a committee of examination. Possibly some of our readers have original solutions of these mysteries if so, we should be pleased to hear from them

THE DARING FEATS OF HARRY HOUDINI

The Current Supplement

THE manufacture of fuel briquettes in this country is a growing and important industry Some significant statistics on this subject have been collected by Edward W Parker, of the United States Geological Survey, and are summarized in an article appearing in the current issue of the SUPPLEMENT, No. 1907—H S Munroe writes on the toxic effects of carbon monoxide—Prof Bickerton contributes a very interesting article on the origin of the Milky Way—Dr Zahm's masterly contribution on aeromechanics is continued in this number—Reginald R Gordon gives a report on the 1912 Convention of the American Railway Master Mechanics' Association. This report is full of important facts, which no one interested in railroading can afford to leave unread.—Our Berlin correspondent describes in an illustrated article the laying of a cable through the River Trave.—Dr Cannon continues his splendid article on Animal Experimentation—Prof. Fleming, the great English electrical engineer, contributes an article on the conductivity of dielectrics.

Copper Mines in Nova Zembla

PROSPECTING for minerals in the Arctic and Antarctic regions is one of the interesting developments of recent enterprise. The latest news under this head is that valuable deposits of copper have been found in Nova Zembla. Funds for working these deposits have been advanced by a banker in [illegible], and a party of engineers and workmen, [illegible] from the Ural, will proceed in a [illegible] steamer to this far northern land.

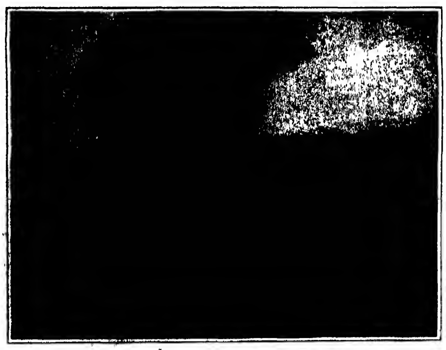
Blowing Up a Locomotive Boiler

Test of a New Type of Safety Boiler

THE statistics gathered by the State Railroad Commission show that every year an average of fifty locomotive boilers explode, causing a damage to property of several millions of dollars and the loss of more or less than one hundred lives, to say nothing of injuries to a larger number of people. The careful investigations which are carried out under the Commission usually lay bare the defects or mismanagement which led to the disasters; but in many cases it is difficult, and indeed impossible, to determine the cause. Low water in the boiler, due to carelessness or oversight on the part of the fireman, accounts for a large number of explosions. Should the water level fall to such a point that the crown, or roof as it might be called, of the firebox is uncovered, the great heat of the fire raises the temperature to a point at which the metal loses its strength and yields under the steam pressure, tearing loose from the staybolts which normally hold it in position.

In the standard type of locomotive, the firebox is held to shape against the inward pressure by tying it to the outer shell of the boiler with a large number of staybolts. Under normal conditions this construction is sufficient for its purpose. But should the crown of the firebox become overheated through the water falling below its surface and exposing it to the full heat of the fire, the heads of the staybolts and the holes in the crown, softened by the heat, are no longer able to hold against the pressure. The bolts are pulled through, and the crown is crushed in. Of all the causes which lead to boiler explosions, this is probably the most frequent. Among the many attempts to build a boiler which would be proof against this form of accident, the most successful is that known as the Jacobs-Shupert sectional firebox, which was built several years ago in the mechanical department of the Santa Fé Railroad Company from the plans of the two engineers whose names it bears. A large number of these fireboxes have been built and are in service on the Santa Fé and other railroads, where they have rendered excellent service. In order to test the qualities of this boiler, it was submitted to investigation by Dr W. F. M. Goss, Dean of the College of Engineering, University of Illinois. Dr Goss is probably the best known authority in work of this kind; and in investigating this particular boiler, it was determined to make a test on a hitherto unprecedented scale, to determine how far it was proof against explosion due to low water, and at the same time to determine whether low water was a sure cause of explosion when it occurred on boilers of the standard radial-stay type.



The explosion of the radial-stay firebox boiler.

The demonstration was made at Coatesville, Pa., on June 20th of this year, before a large gathering composed chiefly of engineers representing various departments of engineering. Two full-size locomotive boilers, designed for high speed heavy passenger service, were each subjected to severe low-water tests. Both boilers were identical in size and design except that one had a Jacobs-Shupert sectional firebox, while the other had an ordinary radial-stay firebox. In carrying out the test, both boilers were mounted in a field, fifty feet apart, and they were operated from a "bomb-proof" located two hundred feet away from the nearest boiler. Because of the danger to which a fireman shoveling coal would have been exposed, oil was used for fuel. Grad-

Rubber Natural and Synthetic

How Will Artificial Rubber Affect the Plantation?

By Prof. F. Willy Hinrichsen, of the Koenigliches Material-Pruefungsamt, Berlin

[The author of this article, Prof. Hinrichsen, has completed for the Koenigliches Material-Pruefungsamt what may well be regarded as a most thorough study of natural rubber, artificial rubber and rubber substitutes. For that reason his comments on the commercial possibilities of the synthetic rubber discovered in Germany deserve more than passing attention. An entirely new significance and interest has been added to the topic by the recent authoritative announcement that a body of English chemists have surmounted the last difficulties in the synthesis of rubber, and have placed it upon what promises to be a sound commercial basis. Prof. Hinrichsen's article was written before this announcement, and is published here in its original form. The reader must supplement his information by reference to our editorial page.—EDITOR.]

IN the last few years the world's consumption of caoutchouc has increased at an extraordinary rate, indeed, so extraordinary, that the supply has not been able to keep up with the demand. The following table statistically summarizes this remarkable increase.

World Production and World Consumption of Caoutchouc.

Years.	World Production in Tons.	World Consumption in Tons
1899-1900	53,348	48,352
1900-1901	52,864	51,136
1901-1902	53,887	51,110
1902-1903	55,603	55,276
1903-1904	61,759	59,666
1904-1905	68,879	65,083
1905-1906	67,999	62,754
1906-1907	74,023	68,173
1907-1908	66,379	62,376
1908-1909	70,587	71,998
1909-1910	76,553	76,026
1910-1911	79,305	74,082

From this table it appears that the consumption of rubber in the year 1908-1909 (the financial year being usually reckoned from July 1st to the following June 30th) exceeded the production. Had it not been for large reserves of raw caoutchouc left over from previous years, the commercial situation might have been alarming.

The Price of Raw Rubber.

This unfavorable relation between production and consumption naturally resulted in a considerable rise in the market price of rubber. The increase in price which would have normally resulted would have been serious enough, but thanks to the stock jobber, rubber brought 12 shillings 6 pence per pound in May, 1910. After that there was a drop. In June, 1911, the price of raw caoutchouc reached a minimum of less than 4 shillings. Then came another increase. The prices that I have here quoted are those for the best quality of Brazilian Para rubber.

The payment of such fabulous sums for natural rubber stimulated efforts to produce rubber artificially, in sufficient quantities and at sufficiently low prices to compete with Para gum. I take it that readers of the SCIENTIFIC AMERICAN are more or less familiar with the methods employed in obtaining natural rubber. Caoutchouc is found in the milky juice (latex) of certain plants, which flows out when the bark is pierced. By proper treatment this milk is converted into caoutchouc. In separating or coagulating caoutchouc the action of heat or chemicals is most important.

Rubber Plantations.

Because the production of natural gum is not sufficient to keep pace with the constantly increasing demand, the more so since whole trees are felled and other most ruthless methods are resorted to, caoutchouc producers have for some years past carried on the cultivation of the rubber tree on plantations. Their rubber may even now be considered the most promising competitor of the wild tree. Enormous areas, especially in Asia (the Malay States, Ceylon, etc.), have been planted with caoutchouc trees. The growth of these trees is rapid, and the amount of caoutchouc annually produced by plantations is constantly increasing. By careful study the most favorable conditions for cultivation—especially the conditions of soil and the most convenient method of coagulation—have been ascertained. In fact, plantation caoutchouc is even now almost as good as Brazilian Para gum. It has brought prices just as high.

More interesting, sensationally so, in fact, is the production of rubber by artificial means, rubber which in its chemical and physical properties is exactly the same as natural rubber.

How Rubber is Made in the Laboratory.

Caoutchouc proper is a compound of carbon and hydrogen, a compound in which these two elements bear the same relation to each other as in a certain well-known class of bodies called terpenes, the main constituents of ethereal oils. From these terpenes some well-known aromatic substances are derived among others. In order to ascertain the manner in which atoms of carbon and hydrogen are fixed in caoutchouc, the chemist must first decompose the caoutchouc, split it up, in other words. If he can do this completely he can obviously discover exactly what elements are required to make caoutchouc. When that mystery is revealed his next task is to take the elements of which caoutchouc is composed and to combine them in the proper way in order to produce artificially a rubber which is chemically the same as the substance obtained from the Hevea tree. Stated thus baldly the problem seems very simple. Yet more than a decade of arduous chemical research has been required before rubber was synthetically produced in the laboratory.

Among the constituents of rubber which are split up by intense heat is a liquid which boils at a low temperature and which in odor and in boiling point closely resembles ordinary ether. That substance is known as isoprene and was discovered by Williams as far back as 1860. Indeed, isoprene proved to be a compound of carbon and hydrogen in about the same proportions as they are found in rubber itself.

Bouchardat, in the course of a comprehensive investigation, found that isoprene, under given conditions, was converted into a substance analogous to caoutchouc. Other experimenters made the same observation later, among them Tilden and Wallach. Frequently, however, the conversion failed to take place. Why? Because the exact experimental conditions which governed the conversion of isoprene into caoutchouc had not yet been ascertained. The failures were so numerous that chemists began to doubt the correctness of earlier observations. It was not before 1909, when F. Hofmann and C. Coutelle, two chemists in the employ of one of the largest chemical works in Germany, found that absolutely pure isoprene is converted into a substance resembling caoutchouc if heated under pressure with and without the intervention of other substances. Independently of these experimenters, C. Harries, at Kiel, discovered the same reaction while heating isoprene with acetic acid.

The Commercial Possibilities of Artificial Rubber.

These experiments have solved the problem of producing rubber synthetically, but as yet only from a scientific point of view. It may here be added that if the initial material be varied in quality and the experimental conditions modified, a number of substances which resemble caoutchouc can be obtained, which are not to be found in nature.

Naturally the business man asks: What is the practical value of this work? Is synthetic rubber merely a laboratory curiosity? Or, can it be produced in marketable quantities at a price to compete with Para gum?

If artificial rubber is to take the place of the natural product, it must be produced more cheaply than Para gum and it must possess all the really essential properties of Para gum. Whether or not artificial rubber can compete with natural rubber depends on so many commercial conditions, it is hard to give a definite answer. Some day it will compete; that much is certain. When that day will dawn, is decidedly uncertain. The struggle is bound to be a hard one. The price of Para gum will surely drop as the caoutchouc plantations are extended and as their annual production increases. The cost of producing a pound of first-class Asiatic plantation rubber is somewhat less than 25 cents. It is possible that even if it costs more to produce artificial than natural rubber, the new laboratory product may have a commercial future if it proves superior in important respects to the natural product.

On the whole, it is not likely that artificial rubber will entirely displace natural and plantation gum, as the coal tar dyes have displaced vegetable dyes. In all probability the natural and artificial products will be sold side by side in the market much as natural and artificial silk are now sold.

The manufacturing cost of artificial rubber depends primarily upon the cost of the raw material from which it is made, isoprene or related hydrocarbons. Patents have recently been taken out to cover processes designed to reduce the cost of the raw material. Isoprene, itself, is obtained not simply from heated caoutchouc but also from turpentine oil and from certain components of coal tar (cresol). Naturally, for practical purposes the isoprene must be obtained from some other source than caoutchouc.

Rubber Substitutes.

Long before artificial rubber was successfully produced various compounds had been discovered which had many of the properties of rubber, but were chemically different from it. Many of these are compounds of oil, shellac and similar substances. Such rubber substitutes, "factices," the French call them, are obtained by treating oils with sulphur chloride, in which case a white rubber-like substance is obtained; or with sulphur alone, in which case a brown imitation rubber is produced. Mixtures of such oil, or sulphur compounds with caoutchouc have proved convenient and serviceable. They seem to last longer than rubber. The imitations or factices themselves, depending upon their process of manufacture, are usually loose and brittle masses of a white or brown color, to be distinguished from rubber by their ready saponification; in other words, they are easily attacked by lyes.

In the patent literature of every country will be found descriptions of plastic masses made from glue, gelatine, cellulose and the like—all alleged to be perfect substitutes for rubber. Some of these have proved of industrial importance. Most of them are valueless because of their inferior elasticity.

Regenerated Rubber.

Foremost among the substitutes for pure rubber may be mentioned regenerated rubber obtained from refuse articles of manufactured rubber. Because of the small supply of natural caoutchouc, the necessity of utilizing the refuse of rubber factories had become almost pressing. According to authoritative estimates, the quantity of old rubber regenerated for the manufacture of rubber articles surpasses the consumption of raw caoutchouc. Such reclaimed rubber is no perfect substitute for new gum. It has lost much of elasticity and strength by the mechanical, physical and chemical processes to which it is subjected. Old rubber shoes, pneumatic tires and the like constitute the raw material from which regenerated rubber is made. When reclaimed the rubber differs in a marked degree from caoutchouc.

Every one knows at this late day that all rubber articles must be vulcanized, in other words, that at certain temperatures sulphur in some form must be added. Although the actual chemical process that occurs when sulphur is thus added is not yet known with absolute certainty, recent investigations show that part of the sulphur compounds are chemically fixed by the caoutchouc. This "combined" sulphur, as it is called, is not eliminated from present regenerated material. In actual practice, the reclaiming or regenerating process destroys the fabrics in the old rubber and converts the remaining vulcanized rubber to a plastic form for further manipulation.

There is no good reason why the sulphur combined with vulcanized rubber could not be removed, theoretically, at least. Most rubber experts, however, have come to the conclusion that the task is hopeless.

Some apprehension has been expressed lest the continual increase in the production of plantation rubber should result in an over-production. Such apprehensions are groundless. Even if the plantations should continue to produce rubber at the present rate, and even if synthetic rubber should also be manufactured, the demand for the natural product will not abate. The quantity of caoutchouc which the world needs is so great that all available sources of supply will be drawn upon. The price, of course, will fall; but that, again, will be offset by increased consumption.

If it were possible for manufacturers to employ synthetic rubber, natural rubber and plantation rubber at very much lower prices than are at present charged, there would be no doubt that the world at large would benefit. The possibilities of rubber are far from being exhausted. The high cost of the raw gum has hitherto limited the applications of one of the most useful substances in the world. When the price of rubber does fall, because new sources of supply have been made available, we may possibly speak of a "rubber age." It is not too romantic to imagine how noiseless would be the street traffic of large cities when rubber becomes so cheap that every vehicle will be rubber-tired, and when even pavements will be made of rubber, which last possibility is not wildly extravagant, inasmuch as rubber pavements have already been used with excellent results.

Inventions New and Interesting

Simple Patent Law ; Patent Office News ; Notes on Trademarks

Cigar-banding by Machine

THERE is usually but one right way of doing a thing as against a large number of wrong ways. In few cases, however, does the disparity between right and wrong ways reach such enormous figures as in the re-packing of banded cigars. The situation is this:

Custom demands that cigars be packed so tightly in the box that they lose their rounded shape and are flattened one against the other. This result is obtained by placing the well-filled box in a mechanical press and leaving it under compression for a number of hours. At the end of that time each cigar is found to possess an individuality of its own. It is unlike any of its fellows. It has yielded here and there to accommodate itself to the crowding and pressing of adjacent cigars. It is of such irregular form that it will not fit in any other position in the box. Obviously, it would not do to band this cigar before it had assumed its final form, for otherwise the band would not fit snugly, and it would be mussed and crumpled in the press. Therefore, it is necessary to remove the cigars from the box after they have been compressed, and band them separately one by one, replacing them in their original container in the same order as they occupied under the press. Unless care is taken to restore each cigar to its original position, trouble is sure to ensue. Once the order is lost, the chances of rediscovering the original arrangement are hopelessly against the operator. Consider a single row of twelve cigars. It is a simple mathematical problem. Multiply 1x2x3, etc., up to 12, and the result will be 479,001,600 different ways in which those twelve cigars may be arranged. If we consider an entire boxful of cigars, the number of wrong ways in which they can be put in the box will reach such a stupendous figure as to pass entirely beyond the comprehension of anyone but an astronomer. Realizing this as well as the fact that objects not uniform in shape are difficult to handle, cigar manufacturers have declared stoutly that the banding of cigars after having been packed could never be accomplished by machine.

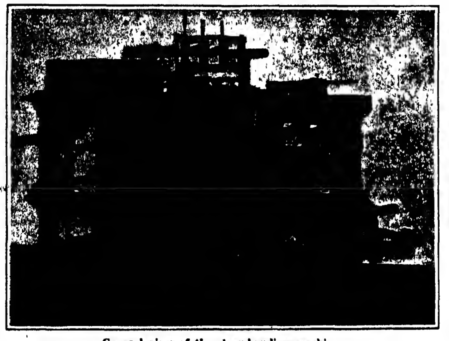
According to the latest report of the Internal Revenue Department, there are some 25,000 cigar manufacturers in the United States, making about eight billion cigars per year, and it is conservatively estimated that fully six billion of these are banded. As all this work is now done by hand, this means that there are six billion separate hand operations requisite. The work is done by girls at almost incredible speed. Yet the cost of banding runs up into the millions of dollars per annum, and imposes a heavy burden on the cigar industry. A number of years ago a banding machine was invented for banding loose cigars. However, as the number of unpacked banded cigars is comparatively small, this machine did very little toward relieving the situation.

About a year ago, we described a machine which had just been built for banding packed cigars. While that machine did actually band cigars, after they had been packed, it was not adaptable to certain special demands of the cigar manufacturer. Accordingly, a second design has been developed, which is shown in the accompanying illustrations. This machine is so improved and simplified as to appear like an entirely different mechanism. It will take the cigars from a box, band each one separately, place the band in the center, or at any other desired point on the cigar, reverse the band for alternate rows, if so desired, and restore all the cigars to the box, doing the work at the rate of about 60 per minute with a single operator, as against two in the old machine.

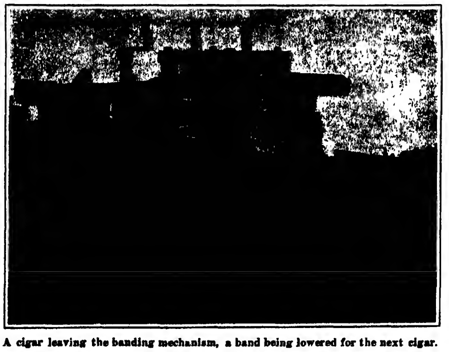
The cigars are removed from the box and placed on a tray without disturbing their relative order. The tray is then placed in the container shown at the left-hand side of one of our photographs, and thence the cigars are moved row by row out upon a receiving table. The most conspicuous object in this photograph is a cam with two broad wings. When the cam roller drops off the point of one of the wings to the base of the other, it acts to eject the bottom row of cigars from the tray. Thereupon the ejector is slowly retracted, until, by the time the first row has passed through the banding mechanism, it will be ready to eject the next row in the tray. The cigars are picked up one by one from the receiving table by a forked suction tube and placed on a pair of fingers or hollow stems of rubber, connected with a vacuum pump, so that they will hold the cigar firmly by suction, yet without danger of injuring the wrapper. Before the cigar is carried to the banding point, a suction finger rises vertically and removes a band from the bottom of a pile placed directly above the banding point. The cigar is then carried over the band and pressed down with it between a pair of spring-pressed guide-plates shown at A in the line drawing, which fold the paper closely around three sides of the cigar. Thereupon a tucker plate B folds one end of the band down upon the cigar. Above the tucker plate is a gumming device, consisting of a tube terminating in an inclined plate C provided with two small perforations. Through these perforations two beads of gum about the size of a pin-head are squeezed out on the plate and are wiped off upon the other end of the band as it is folded down by means of a rubber-coated roller D. At the same time the tucker plate and gumming device are withdrawn, the tucker plate serving to shield the cigar-band from gum scraped off the gummed end. Above the gumming device is a plate E, which serves as a guard to prevent the band from coming in contact with the gum as it is drawn down into position to receive the cigar. While the cigar is being banded the rubber fingers which carry it to that position return to get another cigar, while a second pair of suction fingers take the banded cigar and carry it over to a delivery table. Thus the process is continued until a complete row of cigars has been delivered, whereupon a pusher slide moves the entire row endwise into the tray shown in the foreground of the photograph at the right of the machine. After receiving a row, this container moves down to the proper position for the second row, and when the entire box of cigars has been banded the cigar box is inverted and placed over the tray. It will be noted that the arrangement of the cigars in the tray at the delivery end is exactly the same as that at the receiving end. The box and tray are now revolved together so as to bring the box right side up, whereupon the cigars are forced out into the box, as shown in one of the illustrations. The tray is double, so that when it is revolved to discharge one section, a second section is brought into position, and the work of the machine can proceed without interruption.

In our enlarged view of a portion of the machine may be seen a small hand crank upon a threaded vertical shaft. This shaft forms the plunger rod that projects from the gum cylinder. A ratchet mechanism is operated to feed the plunger down as each cigar comes to the banding position. The amount of gum required for each band is so minute that a reducing gear is required between the ratchet and the plunger. At each operation of the ratchet the plunger is made to move down one ten-thousandth of an inch. The actual amount of gum in each bead on the gum plate is 0.0001 cubic inch. The cylinder is large enough to store a day's supply. To refill the cylinder, the hand crank is operated to withdraw the plunger and thus suck in the gum.

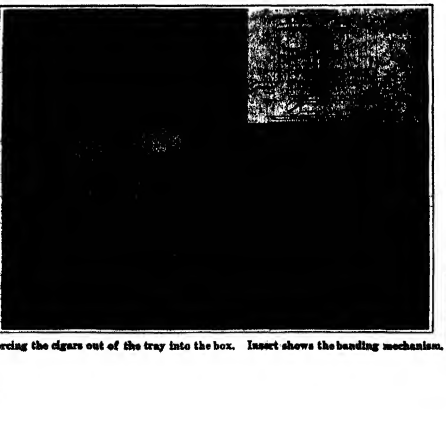
Some dealers prefer to have the bands applied near one end of the cigars instead of centrally. To provide for this an end-stop is used for the ejector slide, and by adjusting this stop with respect to the banding point the position of the band upon the cigar may be determined. When it is desired to reverse the bands in alternate rows, a cam connection is made, which causes the suction finger, as well as the entire banding mechanism, to revolve through an angle of 180 degrees after each band is removed from the pile, thus reversing the position of the band. This reversal will continue for the entire row of cigars, after which the parts will be turned to normal position and there will be no reversal while the next row of bands is being applied.



General view of the cigar-banding machine.



A cigar leaving the banding mechanism, a band being lowered for the next cigar.



Forcing the cigars out of the tray into the box. Insert shows the banding mechanism.

It is customary to pack cigars in rows of 12 and 13 alternately, or in rows of 10 each. The mechanism is arranged to accommodate itself to such packing. The cam shaft which feeds the cigars to the receiving table and controls the feed from the delivery table is moved by a ratchet mechanism. Two ratchet wheels are provided, one of which has 13 teeth on one half and 12 on the other, while the second ratchet wheel has the same number of teeth on each half. When the ratchet pawl is thrown into the former ratchet wheel it will feed the shafts at the rate of 13 steps for one-half revolution, and 12 steps for the other. When, however, the ratchet pawl is thrown into the other wheel, the feed will be uniform. Another adjustment provides for regulating the machine to handle boxes of 25, 50 or 100 cigars. A ratchet wheel with 100 teeth is employed, and if there are 100 cigars to the box the pawl engages 1 tooth at a time, if 50 to the box, 2 teeth at a time; and if 25 to the box, 4 teeth at a time. The machine can thus be adjusted to practically every requirement of the industry.

The Trade-mark as a Business Asset

By W. E. Woodward

[*THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer, that it is a symbol of good will, a tangible asset with a determinable money value, that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.*

The following is the second of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

The Federal Trade-mark Law—II.

The function of a trade-mark is to denote origin.

Throughout its history the trade-mark has remained true to its ancient antecedents, and its purpose to-day, as it was in the fifteenth century, is specifically to indicate the origin of an article of merchandise.

In this aspect of unchanging purpose, the trade-mark is somewhat an anomaly in commercial history. During the last four hundred years, methods of manufacture, distribution and sale have been revolutionized from top to bottom· banks, which began as mere money-changing offices, have become establishments for keeping and loaning funds, the retailer, who used to sit in a hole in the wall with a handful of goods, all of the same kind, has developed into a merchant selling ten thousand different articles, the craftsman, who once served a long apprenticeship, during which he learned to make every part of a shoe or a carriage, has become a specialized laborer, employed by the day to produce the extreme subdivision of a finished article.

The reader should understand clearly that the right to own a trade-mark is not a creation of the statute, for the use of trade-marks, and the recognized right of manufacturers to be protected in their use, far ante-date any specific trade-mark legislation.

The intent of the statute is to systematize and codify trade-mark practice It provides a definite procedure for the registration of trade-marks, lays down rules for validity in marks, puts trade-mark litigation, when registered trade-marks are the subject matter of the litigation, within the jurisdiction of the Federal courts; and makes every trade-mark registered under the law a part of the public records of the nation. But a trade-mark may be legally sound even if not registered, just as a person may own real estate without recording the title.

The ownership of trade-marks, like every other property right, is recognized by the common law. The Supreme Court of the United States has said: "The right to adopt and use a symbol or device to distinguish the goods or property made or sold by the person whose mark it is, to the exclusion of use by all other persons, has been long recognized by the common law and the chancery courts of England and of this country. It is a property right for the violation of which damage may be recovered in an action at law, and the continued violation of it will be enjoined by a court of equity with compensation for past infringements."

Trade-marks, under the Act of 1905, are registered in the United States Patent Office.

In case of litigation resulting over the right to use any trade-mark, evidence of the registration of the mark by one of the litigants puts the burden of proof upon the other. In other words, the user of the unregistered trade-mark must prove priority of use and ownership. This is often a very difficult thing to do, especially in the case of trade-marks that have been used a long time, for such proof must necessarily rest upon the production of old labels, packages of the goods with the trade-mark affixed, and testimony of witnesses

The owner of a registered trade-mark does not need any evidence other than the public records of the Patent Office to establish the date of his first use of the mark.

When a trade-mark is not registered in the Patent Office, litigation concerning it does not come under the jurisdiction of the Federal courts, unless the opposing parties are citizens of different States.

On the other hand, all cases pertaining to registered trade-marks fall within the field of Federal jurisdiction, irrespective of the amount in dispute or the place of residence of the parties. There is an obvious advantage in this, owing to the fact that an injunction secured in one Federal court will be enforced in all such courts in any State.

The fee charged by the Patent Office, under the law, for registering a trade-mark is ten dollars This does not include the attorney's fee, which must be paid by the applicant.

A certificate of registration remains in force for twenty years, and it may be renewed upon expiration, for like periods of twenty years, upon payment of a renewal fee of ten dollars.

An individual or corporation has a right to register a trade-mark under the United States law if the trade-mark for which registration is sought belongs to the applicant and is used by *him*:

1. In commerce among the several States.

2. Or, in commerce with foreign nations.

3. Or, in commerce with the Indian tribes.

Provided the owner of the trade-mark resides within the territory of the United States (which includes all territory under the United States control), or has a business establishment situated in United States territory, or resides in any foreign country which affords, by treaty, similar privileges to citizens of the United States.

Divested of legal verbiage, the main provisions of the Act, so far as the features governing registration are concerned, may be stated as follows:

A trade-mark is not registrable if it is:

A design or wording identical with a registered or known trade-mark owned and in use by another, and appropriated to merchandise of the same descriptive qualities, or which so nearly resembles a registered or known trade-mark owned and used by another and appropriated to merchandise of the same descriptive qualities, as to deceive purchasers, or to be likely to cause confusion in the mind of the public.

The insignia of the American National Red Cross Society.

The flag or coat of arms of any foreign nation.

Any design or picture which has been adopted by a fraternal society as its emblem.

A portrait of a living individual unless the application for registration is accompanied by the written consent of the individual whose portrait is used.

Scandalous or immoral matter of any description.

The flag or coat of arms of the United States, or of any State, or of any municipality, or any of the insignia thereof.

Any geographical name or term.

A misrepresentation of the quality, composition, character, origin, or nature of the commodity with which it is used.

Any mark which consists merely in the name of an individual, firm, corporation, or association, unless said name is written, printed, impressed or woven in some particular or distinctive manner, or is used in connection with a portrait of the individual.

Any arrangement of words or devices descriptive of the goods with which they are used, or of the character or quality of such goods. In other words, a trade-mark must not be an advertisement in the ordinary sense of the word.

A trade-mark is registrable if it is:

Unlike any other trade-mark already in use, and applied to the same class of goods. It must not resemble the trade-mark of a competitor, or of a potential competitor, to such an extent that the buying public is likely to be deceived or confused by the resemblance.

The business name of a person or firm when written, printed, impressed or woven in some distinctive manner, or in association with a portrait, or in an autographic form.

Any trade-mark symbol, or word, or words, or a combination of a device and wording, not obviously descriptive of the commodity to which it is to be applied

Any trade-mark which has been in continuous and exclusive use by the applicant since February 21st, 1895

Used in lawful trade

Of such a character that it may be affixed, printed upon, woven, sewed, branded or otherwise impressed upon the product with which it is used, or upon the package or container of the product

(*To be continued.*)

RECENTLY PATENTED INVENTIONS.

These columns are open to all patentees The notices are inserted by special arrangement with the inventors Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN.

Pertaining to Aviation.

AEROPLANE.—LOUIS F BANCROFT, 36 Pearl St., Hartford, Conn. This invention relates to a novel form of aeroplane, and more particularly to one having automatic stabilizing devices co-acting therewith An object is to provide means for automatically maintaining or restoring the lateral and longitudinal balance of the aeroplane. Further, an object

AEROPLANE.

is to provide an aeroplane having stabilizing surfaces and guiding elements which may be manually operated to convert the same into additional stabilizing elements. The inventor has on many occasions proved that transverse and longitudinal stability of his flying machine has been automatically maintained. The aeroplane is shown in a plan view equipped with a preferred embodiment of the invention.

WING FOR FLYING MACHINES.—G. KOAR, Hamburg, Germany. This invention comprehends a wing having a longitudinal tapering staff made of material more or less resilient, the smaller end of the staff extending to, and in part constituting the tip of the wing, together with feathers, each having a stem and one or more fins extending from the stem, each fin being of composite structure.

Electrical Devices.

INSULATOR.—H. LANGE, Kiel, and F. DRUCKENMÜLLER, Cologne-Nippes, Germany. This invention provides an insulator to be used in connection with high-tension conductors of over-head electric systems for wireless telegraphy and telephony, as well as with supporting tackle used with the masts of wireless telegraph systems, which possesses great strength, is of high resistive power, presents a large surface, is of small circumference and light weight, and which can be inexpensively produced.

DISSOLVING VIEW DISPLAY APPARATUS.—G. T. [illegible], JR., [illegible] Ave., N. Y., N. Y. This invention relates to electrically controlled [illegible] exhibiting apparatus, and its object is to provide a new and improved dissolving view apparatus, in which the display matter gradually appears and disappears to produce a highly interesting effect to the onlooker.

BURGLAR ALARM.—G. DI GIOVANNI, 1488 Washington Ave., Bronx, N. Y. This improvement relates to burglar alarms, the more particular purpose being to provide an electric alarm associated with a number of cords so arranged that the cutting of any cord, or the stretching of any cord, as the case may be, will cause the alarm to be actuated.

SPARK ARRESTER.—B. C. MOXLEY, Box 631, Hoquiam, Wash. Mr. Moxley has for the object of his invention the provision of a simple inexpensive device capable of attachment to any stack without change in the same, and without diminishing the draft, by means of which the unconsumed solid matters ejected from the stack will be held in the arrester.

Of Interest to Farmers.

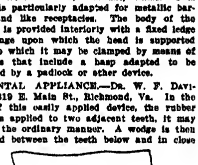
PLOW BEAM.—J. M. RIVERS, Lock Box, 284, Fort Meade, Fla. This invention is an improvement in plow beams and has for an object the provision of a novel construction of metallic beam which will be light, will effectively serve its purpose and will permit the adjustment of the different parts as desired in the practical use of the machine.

BROODER.—G. H. LEE, 1115 Harney St., Omaha, Neb. This invention provides a brooder with a movable or portable hover; constructs and arranges the hover so as to alternately confine the chicks under the hover or to free them therefrom; provides a hover open at the top to receive heat producing and heat retaining accessories if required, and means to limit the extent of the brooder.

Of General Interest.

REMOVABLE HEAD FOR BARRELS AND LIKE RECEPTACLES.—G. W. STAPLES, care of A. W. MARSHALL, Anahuac, Texas. This head is particularly adapted for metallic barrels and like receptacles. The body of the barrel is provided interiorly with a fixed ledge or flange upon which the head is supported and to which it may be clamped by means of devices that include a hasp adapted to be secured by a padlock or other device.

DENTAL APPLIANCE.—DR. W. F. DAVISON, 819 E. Main St., Richmond, Va. In the use of this easily applied device, the rubber dam is applied to two adjacent teeth, it may be in the ordinary manner. A wedge is then pressed between the teeth below and in close



DENTAL APPLIANCE.

proximity to the outer side of the rubber dam until the wedge clamps by its wedging action between the teeth. The inner and the outer ends of the wedge are then bent to secure the wedge in place and to hold the dam out of the way. The illustration herewith presents a front elevation of the invention as in use

DEVICE FOR MEASURING DRAFT ANIMALS FOR COLLARS.—D. S. BROWN, Watertown, N. Y. The object of the present invention is to provide a simple and inexpensive device by means of which the exact measurement of the neck of the draft animal from the largest to the smallest size, may be obtained. When not in use, the device may be hung up, by engaging the hook with a nail or the like, the catch preventing withdrawal of the bar.

NOTE.—Copies of any of these patents will be furnished by the SCIENTIFIC AMERICAN for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

A Hangar Ship

By Capt. W. Irving Chambers, U. S. Navy

I HAVE received numerous requests from leading papers and magazines to supply details of a "hangar ship" which I am credited with having recommended to the Navy Department, and, as the idea of a hangar ship seems to have captivated many who are interested in the development of naval aviation, it seems necessary to publish the facts and to correct a false impression as to my attitude in the matter.

I have never made any such recommendation for the reason that I do not believe that we need such a vessel, even if we could get it. If it is not needed a grave error would be made in asking Congress to consider the proposition.

My views on this subject may be found recorded in the Proceedings of the U. S. Naval Institute for June, 1912, page 745, where, in the discussion of the able article on Naval Aviation by Lieut. Lapointe, of the French navy, I say, "I am quite sure that the majority of our naval officers will agree with this writer on the relative importance of 'capital ships' and auxiliaries."

The reference may be found on page 650 and reads as follows:

"I agree that the navy should be made up of ships, as many ships as possible for the money available. But I also believe that these ships should be of the type to assure victory in battle—battleships—'capital ships.' Cruisers, scouts, destroyers, torpedo boats and submarines are all auxiliary to the battle fleet. Though such auxiliaries are many, their importance must not be exaggerated to the point of spending on them half, or more than half, of our appropriation, as has recently been done. The navy has suffered from a craze for flotillas of useless and costly auxiliaries of every type, whose only reason for existence is a supposed economy.

"A short time ago the true state of affairs was realized, and the construction of torpedo boats and cruisers was discontinued."

And on page 653 he states: "But it is *evidently* a great advantage to have an aeroplane stationed on a ship from which it can be launched and upon which it can land. For such a purpose a *garage vessel* has been proposed to accompany the fleet and shelter a half dozen aerial scouts. But in order to be of any real value such a ship must be a great vessel with enormous deck space and with a speed equal to that of the fleet. The probable cost of 15,000,000 francs would hardly be justified, even if the number of cruisers were reduced. Besides, such expense is not necessary. Modern battleships of the largest size can easily provide space for the launching and landing of aeroplanes without interference with essential features of design or great expense. In addition, an aeroplane can easily be taken apart and stowed below if it be desired to keep it aboard during action—this is hardly probable, however. At any rate, the problem of rising from a ship's deck and landing upon it is now being studied by able minds, and we can expect a practical solution at any time."

My opinion of the "*garage vessel*" is registered in the discussion, page 745, as follows: "Furthermore, the use of a garage vessel would add another of the needless auxiliaries, which according to his reasoning should be avoided."

The ingenious author of the newspaper hoax, referred to primarily, states that "the first hangar ship shall be of size, cruising radius and speed sufficient to enable it to maintain its proper place with either a battleship fleet or a fast scout cruiser squadron. The idea is that aeroplanes may be used far in advance of the actual fighting units, in which case they should, it is said, be carried on a vessel attached to the scouts rather than the real fighters. On this account great speed will be necessary for the hangar ship."

Other details he gives, but the more they are analyzed, the more it becomes apparent that the ideal "hangar ship" is the ideal scout itself. Certainly the scout must have no peer in speed and it would surely be out of the question for one such ship to be of any use in supplying aerial accessories to a dozen or more scouts scattered over an extensive scouting line.

Now it has been my idea from the beginning that all scouts should be supplied with naval aeroplanes and fitted to use them, just as soon as we can determine exactly what is needed for the fittings. This is the idea that prompted the use of the scout "Birmingham" for the first demonstration in flying from a ship.

I go further, however, in believing that all large ships, battleships and armored cruisers, should be supplied with naval aeroplanes, for which there are many important uses other than scouting. But the most urgent reason for placing them on the larger ships first, as soon as practicable, is that it is only by having the aeroplane right in the *midst of the fleet*, in the company of the officers and mechanics who must be made as familiar with it as they are with guns and boats, that we can expect to instruct and exercise our people in its use and thereby study *its efficiency for our purposes*.

The French have designated the "Foudre" as a sort of base hangar for purposes of instruction. Were we to adopt this policy, it would mean the use of any old hulk that could be spared and we would still be confronted with the difficulty of providing the officers and men to man her and the people to receive the instruction away from the ships to which they belong. Furthermore, the policy that I advocate is to have this instruction *going on at every suitable place* where the fleet is apt to assemble, in whole or in part, periodically or permanently.

One "Foudre" could not be in all these places at once and the supplies that she is supposed to carry would be more conveniently carried on board of the necessary auxiliaries, such as the fuel ships, the transports and the repair ships.

In view of our difficulties in getting battleships and essential auxiliaries from Congress, I hope the misguided author of this newspaper hoax will endeavor to correct the false impression that he has created concerning this absolutely impossible special "hangar ship."

However, I do not wish to attribute any but the best of intentions to this author, although he ruffled me a bit by committing me to a preference for the products of a certain factory. But I feel that he must have good intentions because he places me in the category of a "*young officer*," and I am led to hope that it is because he has in mind an essay that I wrote for the U. S. Naval Institute in 1884. I was young then, but, on page 30, Volume XI, may be found the following precept:

"The great secret in naval economy, which many nations have yet to learn, is *to maintain nothing superfluous or inefficient.*"

I am still young enough to stand by that sentence written twenty-eight years ago and, therefore, I do not believe in the "hangar ship."

Growth of the Automobile Industry

THE best way of presenting dry statistics in a form that is both interesting and quickly comprehensible is to use a graphic comparison. Some idea of enormous quantities can thus be readily grasped. Last year the automobile manufacturers of the United States produced 200,000 cars. But how could we possibly show a picture of this vast number of automobiles in the Scientific American and have room for anything else in the same issue? We are forced by circumstances to fall back upon the common method of showing bulk rather than numbers. We have therefore shown in our front page illustration a single car representing the entire output for the year. In other words, if all the material used in the automobiles manufactured last year were put into a single car, the giant product would be 59 times as long, 59 times as high and 59 times as wide as an average machine. Our giant car would tower to a height of 342 feet, or within 100 feet of the top of the Municipal Building which is now being

erected alongside the Brooklyn Bridge. We have had to show this car head-on in the picture, because our page is too narrow for a side view.

The actual number of automobiles in use in 1911 is estimated at 677,000. These, if put into a single car, would make one 660 feet high, and we would scarcely have room on our front page for even a head-on view of the machine.

Though comparisons of bulk are very convenient, we must confess that they do not convey an adequate idea, particularly in products of the nature of automobiles, whose value is represented by the work done upon them rather than by the quantity of material used in them. According to a recent Census Report, the value of the automobile industry in 1909 stood at $249,202,000 for the product and for the value added by manufacture $117,556,000, and in this particular it ranks seventeenth among the big American industries. The same report gives the number of wage earners employed in the manufacture of motor cars, bodies and parts, as 75,721. Our comparison falls short when it comes to showing the number of wage earners and the value of the product. It will be readily apparent to anyone that the giant automobile made up of materials that went into all the automobiles manufactured last year would have a far smaller superficial area and consequently much less hand or machine finished surface than that of all the automobiles considered individually. Consequently, there would be far less labor involved in the making of this huge automobile and the value added to the product by manufacture would be much less proportionately.

The Census Report just referred to gives the per cent of increase of all the big American industries from the year 1899 to 1909. Only fourteen industries show an increase in output of more than 100 per cent, but the motor car industry shows an increase of 5,148.6 per cent in value of product and 3,278 9 per cent increase in number of wage earners. The next best industry in the latter particular is that of electrical machinery, apparatus and supplies which shows a percentage of 107.7, while the second best as regards value of products is 155 per cent shown by the copper, tin, sheet-iron products.

The automobile industry may now be said to have passed its period of infancy and adolescence, and attained an age of maturity. Hitherto there have been such marked changes in design from year to year, that car owners were constantly discarding their old cars and buying new ones. Now the automobile has reached a standard form. Such new developments as are found in the annual catalogue relate to non-essentials and minor details. The man who buys a car to-day may be assured of a machine that will last him for a number of years without growing hopelessly out of date. In the next ten years, therefore, we cannot look for anything like the increase in production that was shown in the decade just past. Despite this fact, however, the automobile industry has not yet reached the peak of maximum production. Our esteemed contemporary, the *Automobile*, after writing to the automobile manufacturers of the country for confidential reports of their output last year and their probable output this year, obtained the figure for 1911, which we have already given as 209,957 cars, and the probable output for 1912 as 247,427 cars. The production of cars in the first two or three months of the year is always higher than for corresponding periods during the balance of the year. In January last 58,422 cars were produced as against 28,581 in January, 1911, and in February of this year 70,242 as against 34,265 last year. Very evidently the estimate of 40,000 odd cars more than last year on the total year's production is not at all too large.

How can this enormous production of cars be disposed of if we accept the estimate of 677,000 automobiles now in use, or one in every 140 of the population? This estimate by the way was very carefully compiled by the *Automobile* and is as reliable as any that can possibly be made. The answer is to be found in our front-page

INQUIRY COLUMN

READ THIS COLUMN CAREFULLY.—You will find inquiries for certain classes of articles numbered in consecutive order. If you manufacture these goods write us at once and we will send you the name and address of the party desiring the information. There is no charge for this service. In every case it is necessary to give the number of the inquiry. Where manufacturers do not respond promptly the inquiry may be repeated. MUNN & CO., Inc.

Inquiry No. 9354.—Wanted, the name and address of manufacturers of lead pencils and pen holders, such as are used for printing advertisements on.

Inquiry No. 9355.—Wanted, to buy a patent roller, a ball-bearing axle, which could be purchased on a royalty basis; it must be cheap and fully proved.

Inquiry No. 9356. Wanted addresses of parties having Pitchblende deposits, if able to ship ore.

Inquiry No. 9357. Wanted addresses of firms selling second-hand water turbines.

Inquiry No. 9358.—Wanted addresses of parties having gum materials to offer in any part of the world.

Inquiry No. 9359.—Wanted to buy a machine for removing the coating of a [illegible].

Inquiry No. 9360.—Want addresses of parties able to ship corundum, garnet, flint, emery or any material suitable as an abrasive.

Inquiry No. 9361.—Wanted, a manufacturer to make card games.

Inquiry No. 9362.—Wanted, to buy a glass which is a non-conductor of electricity, and the address of the makers of the same.

Inquiry No. 9363.—Wanted, name and address of manufacturer of [illegible] stretchers with clamps, which is capable of being folded up.

Inquiry No. 9364.—Wanted, the name and address of manufacturers of Date Pitting Machines.

Inquiry No. 9365.—Wanted, names and addresses of manufacturers of machinery for making picket fences.

Inquiry No. 9366.—Wanted, to buy machinery for fastening wire [illegible] with [illegible] tacks.

Inquiry No. 9367.—Wanted addresses of manufacturers of metal specialties in connection with plate or window glass.

Inquiry No. 9372.—Wanted, to buy a globe for a parlor fountain, working on the Heron system.

Inquiry No. 9374.—Wanted, the name of a manufacturer of a machine to make cushion covers for [illegible] chairs.

Inquiry No. [illegible].—Wanted, name and address of manufacturer of [illegible] patterns of [illegible] job printing presses.

Inquiry No. 9376. Wanted a [illegible] which can be [illegible] at a [illegible] price, [illegible] from $1.00 to $[illegible].

Inquiry No. 9377. Wanted. A machine for [illegible].

Inquiry No. [illegible]. Wanted. A machine for [illegible] from the shell.

Inquiry No. [illegible].—Wanted [illegible] machine for [illegible].

Inquiry No. [illegible].—[illegible] machinery for [illegible].

illustration which shows what an enormous export business is now being done. The automobile was introduced into this country from abroad, but while we used to import large numbers of cars, the imports are now dwindling very rapidly. In the year 1909, 1,645 cars were brought into the country. The next year the import dropped to 1,024, and last year it fell below the 1,000 mark to 972. In the same year our export grew rapidly. In 1909 we shipped out of this country 4,686 cars; in 1910, 8,443 cars, and last year the figures leaped to a total of 15,807. These quantities are shown in the illustration by single cars representing the import and export, respectively, for the different years. It will be observed that the car for 1911 is quite a sizable one compared to the total production of the year. Our illustration also shows the amount of money paid out for imported machines and the amount taken in on exported machines for the same year. This money represents the actual value of the cars and does not take into account large sums taken in for the export of automobile parts and tires. Most of last year's products went to Canada, which took nearly 5,000 automobiles at a value of $5,500,000. Large quantities were also exported to Great Britain, particularly the smaller cars. Census figures place the total at 4,021, valued at $3,380,266.

An advance bulletin just sent out by the Bureau of Statistics places the probable total of exports for the fiscal year ending June 30th, 1912, at $27,000,000 worth of automobiles and accessories parts. During the ten months ending with April 17,000 automobiles have been exported, worth about $16,500,000; and adding to this the value of automobile parts, engines, tires, etc., we have $22,000,000 for the ten months. Only one country in the world exceeds us in exports of automobiles. France sent abroad $24,640,000 worth in 1908 and her trade grew to $31,700,000 last year. In the same period of time our exports grew from $5,000,000 to $20,000,000, and in all probability the United States will take premier position within the next two or three years.

The value and cheapness of the American product is being recognized throughout the world. American automobiles are sold in all European countries and the market is increasing every year. We have an excellent opportunity to sell machines in South America and no doubt this field will be cultivated from now on. It seems, therefore, that although we at home are beginning to use our cars for longer periods and are satisfied with second-hand cars, there will be no curtailing of the output of the automobile manufacturer for a long time to come.

Resuscitation from Electrical Shock

(*Concluded from page 58.*)

Seattle, in June, and adopted, but are still subject to any improvement that may be suggested and is really worth adoption The booklet rules include a section on the 'First Case of Burns," and are to be issued in a flexible cloth cover.

Two other important subjects still remain for disposition. One of these is the approval or recommendation of devices for continuing artificial respiration. The commission has already examined some of the devices obtainable, and will report its conclusions later. It believes thoroughly in the desirability of a practical apparatus which will furnish thorough ventilation of the lungs, for even the best manual treatment may be far from satisfactory or infallibly efficacious. One of these devices has, it is said, proved very effective in its treatment of the lower animals.

But there is left the third great work of the commission. It has followed Goethe's advice in attacking the question that was next or nearest at hand, and has laid down rules that will save many valuable lives. The third task of the commission is an investigation of the possibilities of restoring the fibrillating heart of a shocked person to its natural pulsation. On this part of the subject, Dr. Cannon, president of the commission, in his preliminary official report says: "The electric current may kill

either by temporarily paralyzing the nervous control of the muscles of respiration, or by stopping the regular beat of the heart. When the heart is seriously affected, it ceases to contract as a whole, but continues to contract in parts here and there, so that it appears to quiver. It is then said to 'fibrillate.' In this condition the heart fails to keep the blood circulating, and death quickly results. At present no practical procedure has been discovered which will restore the regular beat of the heart in man after it begins fibrillating. The chief hope of resuscitation for the present lies in proper treatment of the cases of paralyzed respiration, and the immediate necessity in these cases is promptness in applying artificial respiration and continuance of the process until natural breathing returns. In some instances, however, the heart may be merely weakened without being made to fibrillate; then again artificial respiration may be of vital importance, because a greatly weakened heart leads to impairment or total stoppage of respiration, which in turn destroys the last vestige of the heart beat. In all cases, therefore, an attempt should be made to restore natural breathing." Here, then, is a grave problem that has heretofore defined all the resources of medical science. While the efforts of this notable commission may once more be attended with failure, it is well that the attempt is again put forth to win such a boon for mankind. Electricity has done so much to change the older conditions of life and civilization, one is sometimes tempted to appropriate to it the inspired saying: "Behold, I make all things new;" and certainly it never had a nobler field of effort than this to which that progressive body, the National Electric Light Association, has pledged its financial and inventive resources.

Blowing Up a Locomotive Boiler

(Concluded from page 59.)

uated water gages were mounted on the back head of the boilers, and these were read through a telescope which was mounted on the crest of the bomb-proof. Each boiler was brought to a condition corresponding to its regular operation in railroad service, when it has an estimated maximum power of fourteen hundred horse-power, which is equivalent to that required to haul a heavy passenger train sixty miles per hour. The supply of feed water was then shut off, all the other conditions remaining unchanged.

The water level, under the control of the operators, gradually fell, exposing the crown sheet and other portions of the heating surface to the full effects of the fire. Under normal conditions, these surfaces are protected from over-heating by contact with the water; but in these tests the lowering of the water level deprived the plates of this protection and they became red hot.

The boiler with the Jacobs-Shupert firebox was continuously tested under these severe conditions for fifty-five minutes, without developing any failure, notwithstanding the fact that the level of the water fell to a point more than twenty-five inches below the crown sheet. It may have fallen lower, but the water gage glass did not read below twenty-five. The test was then discontinued because the small amount of water remaining did not evaporate sufficiently fast to supply the draft necessary to maintain the fire. At the conclusion of the test, the firebox was apparently in good condition and ready for further service.

The ordinary radial-stay boiler was then tested under conditions identical to those above described. After the test had been in progress for twenty-three minutes, and the water level had fallen to 14½ inches below the crown sheet, an explosion occurred. The crown sheet and the stays which hold it in place, having become highly heated, pulled away from each other and released the pressure in the boiler. The discharge of steam was through the firebox, and the force of the explosion threw parts of the furnace in all directions, and proved sufficient to ...

the entire boiler, weighing forty tons, several feet above its foundation. The boiler was so damaged as to render its reconstruction necessary.

The steam pressure during the Jacobs-Shupert test varied between 215 and 225 pounds for the first twenty-seven minutes, and gradually dropped thereafter until it reached fifty pounds at the end of the test. The steam pressure on the radial boiler varied between 200 and 230 pounds, being 228 pounds when failure occurred.

In the boiler which successfully withstood this severe ordeal the place of the radial staybolts is taken by a series of deep flanges, which extend from the outside boiler shell to the inner shell of the firebox. The firebox shell consists of a series of U-shaped channel sections which are riveted to the inside edges of these flanges. This affords an exceedingly strong construction. Not only does each U-section present an arched form well calculated to carry the pressure, but the very strong riveting of each section to the inner edge of the flanges presents an enormous amount of sectional area to withstand the shearing stresses which must be overcome before the crown sheet can be torn loose and crushed in.

Luminous Phenomena Associated With Earthquakes

THERE is an old and widespread belief that great earthquakes are usually preceded, accompanied, or followed by various luminous phenomena, in the earth or the sky. These are sometimes described as vague illuminations of the air as a whole, glows and flashes of undefined source, phosphorescent clouds, etc.; or more definitely as lightning-like discharges (including fireballs), flames and columns of fire proceeding from the ground, and phenomena resembling shooting stars.

Prof. Ignazio Galli, of Rome, has taken the trouble to collect descriptions of these phenomena from all available sources, and has made them the subject of an elaborate memoir, originally published serially in the *Bolletino della Societa Sismologica Italiana*, and subsequently issued as a separate pamphlet of 230 octavo pages. The author cites textually 148 cases, dating from before the Christian era to the 20th century. Of 130 cases, 27 occurred by day and 103 by night. An analysis of 109 earthquakes shows that 52 were preceded, 37 accompanied, and 20 followed by luminous phenomena. In connection with the great Calabrian earthquake of 1905, such phenomena were reported from 42 localities, chiefly as having occurred before the earthquake.

Undoubtedly many of these phenomena were ordinary lightning flashes accompanying thunderstorms. When a quake occurs in a town, concomitant luminous phenomena may easily be explained as the result of fires breaking out in buildings, the sparking of crossed electric wires, etc. Other cases may be attributed to the ignition of subterranean gases, released by the rupture of the ground. There seems, however, to remain a minority of cases, especially when the luminous appearances preceded the earthquake, in which none of these explanations apply. As to the luminosity of clouds and fog, this phenomenon has often been reported, but by no means exclusively in connection with earthquakes.

Commenting on Galli's memoir in the *Comptes Rendus*, Comte de Montessus de Ballore, director of the Chilean seismological service, gives an analysis of 135 reports received in connection with the great Chilean earthquake of August 16th, 1906. After this earthquake question blanks were sent to all parts of the country, and among the items of information requested was a report as to the occurrence and character of luminous phenomena. Unfortunately for the particular object in question, severe thunderstorms prevailed in Chile at the time of the earthquake, and a majority of the luminous appearances reported must be attributed to ordinary lightning. The author does not consider the question whether these widespread thunderstorms might be themselves connected in some way with the earthquake.

Munn & Co., Inc., 361 Broadway, New York

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest If the photographs are sharp, the articles short and the facts authentic the contributions will receive special attention Accepted articles will be paid for at regular space rates

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement

The Senate Bill for Safe Ships

THE bill introduced in the Senate by Senator William Alden Smith who conducted the Titanic inquiry commends itself to the serious consideration of the owners and builders of ocean going steamships and the general traveling public

It was inevitable that several bills relating to the subject would be introduced in Congress Some of these call for measures which are impracticable but the bill of Senator Smith shows that whatever criticisms may have been made of his methods of conducting the Titanic inquiry he has very clearly learned the lessons of the great disaster both as to the causes which led to it and the remedial measures which must be taken to prevent its possible recurrence

The SCIENTIFIC AMERICAN has claimed from the very first that the most important lesson taught by the disaster was that present methods of constructing large ocean going steamships do not make adequate provision to protect their flotation in the event of collision So far as her strength was concerned the Titanic was a most excellently constructed ship The great defect in this vessel and in at least 95 per cent of the merchant ships afloat to-day is that the provisions against sinking such as bulkheads water tight decks and the double skin are altogether too few and such as exist are insufficiently worked out

Therefore we are glad to note that the Smith bill calls for the inclusion in ocean and coastwise steam vessels of certain safety elements designed to protect the flotation which as we have shown in these columns would have saved the Titanic had they been present within the structure of that ship If the bill becomes law it will be necessary for every steel ocean or coastwise sea going steam vessel and every steel steam vessel navigating the Great Lakes carrying one hundred or more passengers to have a water tight skin inboard of the outside plating This skin must extend not less than 10 per cent of the load draft above the full load water line either as an extension of the inner bottom plating or in the form of longitudinal water tight bulkheads and it must reach from the forward collision bulkhead over not less than two thirds of the length of the vessel

The transverse bulkheads are to be so spaced that any two adjacent compartments of the vessel may be flooded without destroying its floatability or stability We could wish that the bill read any three adjacent compartments for it is certainly conceivable that collision with another ship or a long tearing wound such as that received by the Titanic whether through the side plating or through the double bottom might fill at least three compartments

The transverse bulkheads forward and abaft of the machinery spaces are to be continued water tight vertically to the uppermost continuous structural deck and this deck is to be fitted water tight Bulkheads within the limits of the machinery spaces must extend not less than 25 per cent of the draft of the vessel above the load water line and they must end at a water tight deck

Applying the foregoing regulations to the Titanic it would mean that the first four and the last three bulkheads would be carried up to the shelter deck about 40 feet above the water line and the bulkheads throughout the engine and the boiler room spaces would be carried to the upper deck to a height of about 10 feet above the water level

Finally all water tight bulkheads and decks must be proportioned to withstand, without material permanent deflection, a water pressure equal to five feet more than the full height of the bulkhead. Bulkheads of novel dimensions or scantling are to be tested by actual water pressure. The bill would be improved if this read that all bulkheads before being passed by the surveyors should be tested by actual water pressure

The bill as we have said, makes excellent provision for safeguarding the flotation of future ships. We suggest, however, that it would be much improved if a clause were added stating that all openings leading from the boiler and engine rooms and the holds to the shelter deck must be inclosed in steel water-tight trunks, or casings. This provision should be so worded as to apply to openings for boiler uptakes, ventilating shafts ladders and cargo hatches. The provision of such casings would prevent water, which might enter the ship below the water line, from rising above the water tight deck and flooding the decks above.

The Royal Society

ALMOST every eminent Englishman seems at some time to have tossed into a hat a handful or so of that form of carbohydrate food used in the making of "alphabet soup" to have taken out at random, just as from a church fair "grab bag,' a number of these letters and have suffixed them in a long string to his natal and baptismal cognomina. Among these seemingly adventitious combinations the most highly prized by Englishmen of science is that denoting fellowship in the Royal Society of London for Improving Natural Knowledge This superb institution—when time presses called simply the Royal Society—on the 15th of July celebrated its 250th anniversary It was founded by Charles II, of otherwise rather nebulous memory, and all his male successors on the British throne have been members, including the present King, who evinces a very active interest in its welfare and in its beneficent deliberations

Representatives of the French Academy, which Cardinal Richelieu founded only a few years before the Royal Society, attended the anniversary celebration The Society seems to have been originated, not by an Englishman, but by a German—Theodore Haak, who came from the Rhine Palatinate and instituted in 1645 weekly meetings 'of divers worthy persons inquisitive in natural philosophy and other parts of human learning, and particularly of what has been called the new philosophy, or experimental philosophy," and another German, Heinrich Oldenberg, was the first secretary Three years later a sister organization, the Philosophical Society of Oxford, was founded in that university A most friendly intercourse was maintained until, in 1660, under the chairmanship of Dr Wilkins, their activities were joined in a metropolitan corporation for promoting 'physico-mathematical, experimental learning and philosophy" Sir Robert Moray was the first president, and among others have been Newton and Lister Several great Americans have been or are fellows—Benjamin Franklin, Benjamin Thompson (Count Rumford), Alexander Agassiz, Simon Newcomb, Dr S Weir Mitchell

The membership has from the beginning been limited to fifty-five, most of these famous men have ever been and are advanced in years on joining the Society, such fellowship meaning to them the crowning point of a career devoted to science And there are fifty honorary foreign members, without power and selected by the council from among men eminent in science abroad. The annual election of officers is held on the day of the Society's spiritual patron, St Andrew It receives from the British Government an annual grant of £5,000 A report on its considerable trust funds and its other sources of revenue is published annually Its expenditures are for the public weal, every year thousands of pounds are devoted to the promotion of scientific research, and to paying for the experimental work of scientists who personally lack the means Through its long and most honorable existence, it has ever been the principal advisor of the State and Crown in all matters of science It is officially represented on the governing body of every kind of governmental and semi-public scientific and other educational institution Its counsel is sought and given on matters innumerable. It keeps ever in touch with learned societies throughout the world.

It has the custody of the standard copies of the Imperial Standard yard and pound, it controls the National Physical Laboratory, which was established by the Government on its recommendation; it superintends the Kew and the Greenwich observatories, on its initiative, and by its advice, the Government inaugurated the geodetic survey in 1791 Other enterprises which have had the Society's aid are the expedition of Capt Cook to observe the transit of Venus, and that great commander's circumnavigation of the globe; the various Arctic expeditions under Ross, Parry, Franklin, and Nares, the "Challenger" expedition; the International Congresses on the questions of a prime meridian, and of an international seismological investigation system, tidal observations, protection of buildings from lightning; tropical diseases, color-blindness; and much else impossible of enumeration.

The Conquest of Disease

THE Health Department of New York is to be congratulated upon the [illegible] rate in New York from [illegible] the forty-six years covering the period since the department was organized. In the year [illegible] the death rate ratio was 36.31 per each thousand of population. To-day the ratio is 15.13 per thousand.

Well may the report say "The facts are significant. They show in an unmistakable manner the success of public sanitary administration which has directed its efforts almost entirely against infectious diseases."

Peace hath its victories—and surely this successful conquest of disease is one of the greatest of them. Our satisfaction in contemplating a reduction of over 50 per cent in the death rate of New York, our admiration for those thoughtful, highly intelligent and always industrious men who, in the quiet of the laboratory, have been carrying on the fight against disease, becomes the greater when we remember that what has been done in this city has been done also in a hundred others

A reduction of over 50 per cent in less than fifty years in the death rate justifies, surely, the hope that before another fifty years has passed science will have obtained a complete mastery of infectious diseases, and mankind, once the prey of superstition and a predisposing dread, will have realized that, if certain simple salutary laws are followed, it can live its day-by-day life free from all fear, even of the great white plague itself.

Certain diseases there are which to-day remain unconquered, chief among which is the last-named. Yet even these are gradually being brought under control, and the progress in bacteriology, particularly during the past decade, has been such that, even in the laboratories (where predictions are never made) one can detect a note of strong hopefulness that consumption and the few other of the diseases which have hitherto stubbornly withheld their secrets, will be brought within absolute control

It is an amazing fact that the very methods by which the bacteriologist has achieved his wonderful success are being bitterly attacked. Had it not been for the practice of vivisection, this 50 per cent reduction in the death rate could never have been accomplished So far from the bacteriological investigations which have been made in the laboratories of this and other cities being marked by needless cruelty, the discomfort or pain which may have been suffered by a certain few dumb animals has brought untold benefit and relief.

The Exiles of the South Orkneys

THE heroism of the cosmopolitan group of scientific men that keeps in operation the Argentine meteorological station in the South Orkneys attracts surprisingly little attention, even from the scientific public The station was originally established by the Scottish Antarctic Expedition of 1902-04 and was taken over in 1904 by the Argentine Meteorological Office Every year a party of four—three observers and a cook—is sent out from Buenos Aires to spend a year of exile in this inhospitable spot, which, although north of the Antarctic circle (lat. 60 deg. 40 min), is generally ice bound, and has a truly polar climate. The mean annual temperature is 23.8 deg. Fahr The snowfall is excessive, sunshine is rare, and strong gales are frequent. Moss and lichens are the only vegetation.

From a purely scientific point of view, the study of the winds and barometric pressure distribution of the Antarctic is peculiarly interesting on account of its comparative simplicity The South Pole lies at about the center of a dome-shaped continental glacier, so that the wind-system belonging to the planetary circulation and that due to air drainage down the glacier slopes are approximately concentric.

It is urgently desirable that other fixed and permanent meteorological stations should be established in the south polar regions. Pending this consummation, the enlightened policy of the Argentine government in maintaining a station in the South Orkneys, at a cost of from $20,000 to $25,000 a year, is most commendable. Special praise, however, is due to the devoted men, of several nationalities—Scotch, American, and others—who are unobtrusively carrying out this important undertaking, with all the hardships it involves They richly deserve the tribute paid to them by M. Rouch, of Dr. Charcot's last Antarctic expedition, in a recent address before the Société Météorologique de France:

"There, for a year, in a primitive house, amid continual storms, never sure of the return of the ship, which, in order to reach them, must sometimes penetrate a difficult ice pack, they lead the traditional existence of a polar winter sojourn; obliged to bear every drudgery and to endure a rigorous climate. They do not call themselves polar explorers, and on their return to civilization they do not go about the world delivering lectures—hence they are unknown. [illegible] that I pay this tribute of my admiration to these men"

Engineering

New French Dreadnoughts.—The French navy is following the lead of Great Britain and the United States by increasing the caliber and reducing the number of guns in her main batteries. The three new battleships, the "Lorraine," the "Bretagne," and "Provence," of 23,500 tons, will carry ten 13.5-inch guns, all placed on the longitudinal center line of the ship.

The Largest Warship.—Although authorities differ as to the dimensions of the recently-launched British battle-cruiser "Queen Mary," there seems little reason to doubt that she is the largest warship afloat at the present time. Some authorities give her dimensions as follows: Length over all, 725 feet; beam, 87 feet; and displacement, 29,000 tons. She will probably make over 30 knots on trial, and to do this her turbines will have to develop not far short of 100,000 horse-power. The "Moltke," of 23,500 tons approximate displacement, required 90,000 horse-power to drive her at from 29 to 29½ knots.

Thirty Miles of Warships.—Great Britain has been the scene of some remarkable naval mobilizations, of which, until this summer, the most notable was that held during the coronation festivities last year. In point of size, however, that review was surpassed by the one held at Spithead last month, when 239 warships, big and little, were drawn up in six parallel lines, which, if strung out in single line, would have extended for 30 miles. The significance of this display will be appreciated when it is remembered that Great Britain is building warships at a faster rate, and is building more of them, than at any period in the history of her navy.

Scouting by Submarine Bell.—Four of our naval submarines, using the submarine bell as the only source of communication, recently went in search of the "Castine," which represented an enemy's ship. The submarines maneuvered in depths of from 20 to 60 feet, and finally the "Castine" was found and theoretically sunk by four torpedoes provided with dummy heads, which were successfully discharged at the ship. It may be mentioned that the submarine bell affords effective protection against collision, since the throb of the engines of an approaching ship can be distinctly heard when the submarine is below the water.

"Titanic" Inquiry Concluded.—The Board of Trade inquiry into the "Titanic" disaster has been concluded, and its President, Lord Mersey, has announced that its report will be produced "within a reasonable time." The Attorney-General referred to the inaction of Capt. Lord, of the "Californian," and said that he had come to the conclusion that there was no excuse to be found for his conduct on that night when, as the evidence showed, his ship might have reached the "Titanic" in time to save the whole of her passengers. He asserted that utterly unnecessary risks had been taken by the "Titanic," and that the causes of the disaster were a bad lookout and excessive speed.

A 32-knot Steam Yacht.—The turbine yacht "Winchester," built for P. W. Rouss, Esq., of New York, by Yarrow & Co., under the supervision of Cox & Stevens, naval architects, New York, ran her full speed trials recently on the Skelmorlie deep water measured mile, attaining a mean speed of 32¼ knots. This was a quarter of a knot in excess of the contract speed. The "Winchester" is 205 feet in length and 18 feet 6 inches in breadth, and the trials prove her to be one of the fastest yachts afloat. The propelling machinery consists of Parsons turbines, driving two shafts, and steam is supplied by two of the firm's water-tube boilers fired with oil fuel.

Hydraulic Transmission for Diesel Motors.—The Vulcan Company, of Stettin, are building two Föttinger transformers, capable of delivering 1,200 horse-power, for a vessel to be employed in the Congo trade. It begins to look as though the introduction of Diesel engines on ocean-going ships, particularly those engaged in freight carrying, will produce a widespread demand for an efficient speed-reduction mechanism. Three types are available—the mechanical, the electrical and the hydraulic. The mechanical leads in efficiency, the electrical in the wide range of speed control, and the hydraulic reduction gear, although lower in efficiency than the others, has the advantage of quick reversing, a wide range of speed and great reliability.

Memorial to "Titanic's" Engineers.—One of the most striking instances of devotion to duty in the "Titanic" disaster was that afforded by the engine-room staff. In a sudden emergency, such as overtook this ship, the order for the engineer staff is "all below;" and, judging from the fact that not a single member of the staff of thirty-four, including John Bell, the Chief Engineer, survived the disaster, it is believed that every one of these men remained at his post to the very last and went down with the ship. Engineers the world over are invited to contribute to a Shilling Fund (25 cents) to erect a suitable memorial in Southampton. Contributions will be received in the United States by Mr. H. L. Aldrich, *International Marine Engineering*, 17 Battery Place, New York city.

Aeronautics

Newest Record for Speed.—Vedrines traveled for two hours at a speed of one hundred and six miles an hour at Rheims, on July 18th. He broke all records.

The Wright Hydro-aeroplane School.—Orville Wright has decided to open a station at Glen Head, L. I., where the use of the hydro-aeroplane is to be taught. The station will be in operation, it is said, on or before August 1st.

The Aeronautic War Fund of France.—According to *Le Temps* the National Committee for Military Aviation has collected the sum of 1,280,373 francs for aviation purposes. The National Committee has already turned over to the Ministry of War the sum of 500,000 francs for the purchase of thirty-three aeroplanes.

A Hydro-aero Bus.—Roger Sommer has built a hydro-aeroplane which is to carry six passengers. The machine is to be used on Lake Geneva. Tickets will be sold to tourists. The maximum speed is to be only forty-five miles an hour. Daily circuits are to be made from town to town around the lake.

Japan Buys Aeroplanes in America.—It has been announced at the office of Glenn H. Curtiss that the Imperial Japanese Navy has placed an order for three hydro-aeroplanes, and that three Japanese Navy officers are now on their way to Hammondsport, where they will be taught to fly the machines.

A Glenn Curtiss Launching Machine.—Glenn Curtiss, the well-known aviator, has secured a patent (No 1,027,242) for a means for launching flying machines, which comprises a suitable mount with an aeroplane supporting device pivoted upon it, in connection with which he provides means for imparting at a variable speed an angular throw to the supporting device so that the machine is brought to a position after it has attained a maximum velocity which position is according to the proposed direction of flight.

Aeroplane Fleets for Argentina and Roumania.—The recent popular movement in Italy whereby the army of that country became possessed of a fine fleet of aeroplanes has had parallels in Argentina and Roumania. It is reported that the Sociedad Sportiva Argentina has offered the Minister of War an aerial fleet, the cost of which will be defrayed by the sale to the public of 1,500,000 illustrated postcards. A competition was recently held to obtain suitable designs for the cards, viz., allegorical representations of the military uses of aviation. An Aerial League has been formed in Bucharest for the purpose of raising funds by popular subscription with which to buy aeroplanes for the Roumanian army.

Do Flying-fish Fly?—This much-mooted question is discussed by William Allingham in the *Nautical Magazine* The orthodox scientific opinion is that the "wings" of the flying-fish merely serve as a parachute to sustain the fish for a brief period in the air, after he has launched himself out of the water by a powerful screw-like movement of his tail. According to this view, the fish has no power of directing his flight after he has left the water However, Mr. Allingham, who is a nautical expert attached to the British Meteorological Office and is in constant intercourse with seamen, reports many observations that tend to controvert this opinion. Certain observers claim that the wing-fins are in constant rapid vibration, and seem actually to serve the purpose of flight. One vessel master watched a fish that had attained an altitude of 20 feet above the water, and was flying toward the mizzen rigging of his ship when, apparently noticing the obstruction, it changed its course about 60 degrees, crossing the vessel's stern to regain the water. Many other similar observations are mentioned. A series of cinematograph pictures might solve this question once and for all.

Death of Hubert Latham.—Hubert Latham, one of the pioneer aviators, was killed by a buffalo on June 7th in a hunt in the French Soudan. He was one of the few men who first took up aviation and who was still flying almost up to the time of his death. The rest have either been killed or have gone into the safer vocation of manufacturing. Latham took up flying very soon after Wilbur Wright made his demonstrations in France. He always flew an Antoinette monoplane. He had not been flying many months before he decided to cross the Channel. His first attempt was made on July 19th, 1909. He flew half-way across and then fell into the sea and was picked up by a French torpedo boat. After Blériot had performed the feat, Latham made a second attempt on July 27th, covering nineteen of the twenty-two miles. Just off Dover he again fell into the Channel. Latham was phenomenally lucky. He emerged time and time again from accidents without serious personal injury, although he smashed machine after machine. In his day he was a record breaker. He held records for endurance, height and speed, all of which, however, have since been broken. Americans will remember him as one of the contestants on the French team that competed at Belmont Park in 1910.

Automobiles

When Kerosene is Useful.—A motorist from Marion, N. Y., the other day was caught miles away from a garage, without a drop of gasoline on which to get home. Inquiry at farm houses nearby failed to reveal any available supply of the "precious fluid," and so he decided to try a can of kerosene. As the motor was still warm, he had no difficulty at all in starting it and finishing his run home without further trouble.

Folding Chairs of Pressed Steel.—Folding chairs made of pressed steel, which can be folded together so as to look like an ordinary music holder, and slipped into a cover, are the latest in the accessory business. Although the weight of the chair is but thirty ounces, it is built strong enough to support a man weighing four hundred pounds

Nickel Trimmings Now Popular.—A large proportion of the 1913 output of the American automobile companies will have nickel trimmings The beauty and durability of nickel, and the ease with which it is kept bright, commend its more general use. At any rate, it is a tasteful compromise between the brilliance of burnished brass and dull effects of the more utilitarian finishes, such as gun metal

Subsidizing Motor Cars.—The British War Office has drawn up a provisional scheme for subsidizing "petrol motor lorries" (i. e., gasoline trucks built for carrying heavy loads) built after January 1st, 1910, and owned by civilians. The owners are to receive an initial subsidy varying from $39 to $58, and an annual subsidy of $73, in return for which they are to agree to turn over their wagons to the government in case of war, at a fixed price.

Reinforced Bulb Horns.—Because the ordinary bulbs used on automobile horns have invariably been a source of trouble and annoyance to the motorist, and because the various mechanical horns are making such a remarkable progress, a French horn maker has brought out a reinforced bulb for the ordinary reed horn, which has several unusual features. Instead of being smooth and slippery, the new bulb is ribbed horizontally and vertically, affording a good grip to the fingers and strengthening it to such an extent that it will outlast three ordinary bulbs.

Race Victories and Sales.—The public, of course, well knows that race victories influence to a certain extent the sales of cars, particularly of those of the "roadster" type But it must come as a distinct surprise to hear of a German factory which by good judgment and good luck managed to win three successive road races and one reliability tour, whereupon it received a cable order from England for no less than eight hundred chassis of the winning type. Previous to the winning of these races the entire output of the factory amounted to only one thousand cars.

Dual Wheels for Heavy Cars.—Instead of mounting dual rubber tires on a wide-rimmed wheel, for use on heavy-duty trucks, a New York tire expert has invented a dual wheel, which is said to have shown great efficiency in the trying-out process The wheels are staggered, one spindle being in front of and the other behind the line of the axle The spindles are connected by means of an equalizing bar, which permits the wheels to follow the contour of the road and equally divides the load between them. While the wheel is to be made in New York by a well-known rim manufacturer, it is based on patents which were granted to Molesworth, the British scientist The invention was improved and developed by Alexander Dow.

Emergency Steering Device.—Many of the most serious accidents in fast driving, and especially in racing, arise from the breaking of the steering knuckle and the subsequent swerving of the front wheels. A Rochester mechanic has patented a device which is designed to prevent the swerving of the wheels in the event of a fracture of the steering gear. The device is practically a double steering gear, operating independently. The main gear is attached to the machine and the second gear can be put on if desired. The former operates on a knuckle joint, while the latter acts directly on the wheels. A steering post is fastened directly beneath the steering wheel, and operates on a worm screw connected with rods on which are bolted collars set in a flange bolted to the wheels. The flanges are constructed so the collar rests in them and runs on ball bearings, the two wheels being connected by rods across the front of the machine, in addition to the usual tie rods. If the main gear breaks, the rods hold the wheels from swerving and steer as if nothing had happened. If one of the rods of the device breaks, the other will do the work. If a nut comes off one of the wheels, the flanges and collars will tend to prevent the whole from coming off, and even if the axle should break, the device will do its share toward preventing a bad smash-up; the machine will rest on the rods and give the driver a chance to come to a stop without turning a somersault.

Fig. 1. A Central American Indian woman, a white boy and a negro photographed with ordinary light.

Fig. 2.—The same subjects photographed with invisible ultra-violet light.

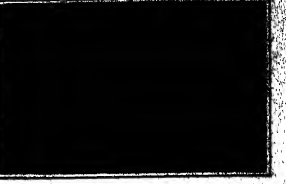

Fig. 3.—This photograph was made with infra-red light.

Black and White Men in Invisible Light

Tricks Played by Ultra-Violet Rays

By Gustave Michaud and Fidel Tristan, Costa Rica State College

SEVERAL hypotheses have been advanced to explain the difference in color between the southern and northern races of mankind. None is entirely satisfactory. It occurred to the writers that some progress might perhaps be made toward the solution of the problem if the relative absorption of light by the white and colored skins was considered not only for the visible radiations, but also for the invisible yet ever-present ultra-violet and infra-red lights.

A group composed of a dark-skinned negro, an Indian woman of a chocolate color with perhaps an admixture of negro blood, and a white boy of Alpine descent was photographed successively in visible light, in infra-red and ultra-violet lights. Foucault's filter (3,100 to 3,200) was used for the ultra-violet, the objective being a quartz lens silvered on both sides. Exposure in full sunlight 3 minutes. For the infra-red, Prof. Wood's filter was slightly modified, the 15-gramme gelatin filter made by Messrs. Wratten and Wainright, of Croydon, England, was placed between two disks of cobalt glass of the darkest shade used by oculists. The spectrum panchromatic plates, sensitive to the infra-red, and made by the above named firm, gave a tolerably good image with an exposure of 7 minutes.

The result was of a somewhat unexpected and confusing nature and is clearly told by the accompanying three photographs. The difference in the absorbing power of the black and white skins decreases from the infra-red to the ultra-violet. In the infra-red it is by far greater than in visible light. In the ultra-violet it is almost *nil*. Indeed, it may be said that, if our eyes were sensitive to ultra-violet light only, all men would be negroes, so far as color is concerned.

Some years ago, one of the writers (SCIENTIFIC AMERICAN, November 5th, 1904) ventured to explain the genesis of the white races of men through a process similar to that which bleached the fur of most northern animals which hunt or are hunted. During the whole Paleolithic and great part of the Neolithic ages, man was ignorant of agriculture. In Abbeville, in Spy, in Mentone, in Hoxne, in the caves of Périgord, numberless flint or bone implements were found which prove that fact. The Paleolithic man was a hunter, and this being recognized, it becomes easier to explain how his color was changed, like that of other northward-migrating carnivora, than to explain the reason why he should have been an exception to the general rule. Primitive tribes were probably often decimated by hunger, as the Canadian Indians of to-day. Those hunters who exhibited on the snow a sallow face, black hair, beard and eyes worked at a disadvantage when compared with somewhat lighter-complexioned comrades. They were more conspicuous on the white field, and could not so easily approach their prey within striking distance. When food was scarce, mortality was the greatest in their families; the lighter-complexioned individuals leaving in every generation the larger posterity. If that explanation holds good, it is rather easy to understand the reason why the selective process which decreased the absorption of visible light by the skin had no such influence on the invisible ultra-violet light. Why and how the same process should have deprived the white skin of the power of absorbing the warm and invisible infra-red radiations is by far more difficult to understand. It seems that such radiations are needed above all by the man who must withstand the effects of a cold climate. Yet the negro is the man whose skin is so organized that it can absorb them.

"Heart Stopping" as a Profession

Examples of Muscular Control of Scientific Interest

By John B. Huber, A.M., M.D.

A MAN recently exhibited himself in London, who, according to an imaginative press-agent, gave "an extraordinary demonstration of phenomenal muscle manipulation and stopping the beating of the heart," before members of the medical profession in London. I cannot find, however, any report of this demonstration. The press agent states that "by years of hard work, careful study and immense concentration of mind," the athlete in question "can manipulate his muscles to an extent never before deemed possible in medical history." Many men have by exercises developed enormous muscles, but they have been invisible and remained firm to the touch even when relaxed. But this athlete can relax his muscles to such an extent that "by shaking his arm he can make the triceps quiver like reeds shaken by the wind." More than this, he can stop the beating of his heart for more than twenty seconds, and retard or accelerate his pulse at will, thereby defying the laws of nature. There is no authentic case of this feat ever having been accomplished before. In the second of the photographs here published the flesh has been drawn tightly into the throat and up under the under jaws, by muscular contraction, "all being as solid as a block of marble." In another the muscles of the neck are made distinct. Still another shows unusual manipulation of the abdomen. The athlete "can draw in his stomach to an extraordinary degree and also protrude it as much in the opposite direction."

It is also claimed that this performer can remain under water from six to eight minutes, and that he can live for a protracted time when buried in the ground.

(Continued on page 85.)

2.—The flesh drawn tightly into the throat by muscular contraction.

3.—Appearance of a curtain produced by muscular control.

4.—The abdominal muscles contracted [illegible] concavity.

The "Commonwealth"-"New Hampshire" Collision

The Bulkhead and the Watertight Deck Prove Their Value

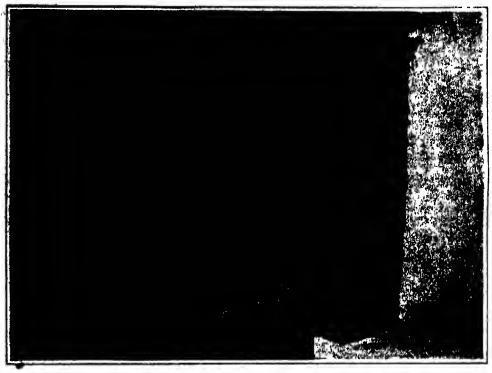
IT would be difficult to find a better example of theory borne out by actual practice than occurred in the recent accident to the U. S. S. "New Hampshire" when run into by the Fall River Line steamer "Commonwealth."

The accident occurred in Newport harbor about 5 A. M. on the morning of July 7th. The battleship "New Hampshire," displacement 16,000 tons, was lying at anchor in a heavy fog, when the "Commonwealth," one of the most palatial of modern steamers, with a displacement of about 4,500 tons, rammed the stern of the battleship at a point about six feet to starboard of the center line. Chance could hardly have chosen a better point for the collision to occur, for, in spite of the fact that the "New Hampshire's" full crew was about 750 men and the "Commonwealth" was probably carrying an equal number of people, not a single fatality or injury of any kind resulted.

The general extent of the damage to each vessel can be observed roughly by referring to the two photographs, and it will be seen that as usual the body receiving the blow has suffered considerably more damage than the body inflicting the blow. At first sight, it would seem that Newton's law of motion, "Action and reaction are equal and opposite in direction," is not evidenced here. Just here though the point is frequently overlooked, that in addition to the structural damage to the "Commonwealth," *the speed of her great mass was reduced almost immediately to zero*, and it is this consideration that brings the theory and practice in accord. Some idea of the force of such a blow can be approximated from the following calculation. In the absence of any definite information on the subject, assuming a speed of 15 feet per second (corresponding to slightly over eight knots per hour, which is considerably less than half speed for the "Commonwealth"), and a displacement of 4,500 tons, we find that the energy of the blow which she delivered against the "New Hampshire" was about 16,000 foot-tons. This would be sufficient to lift the battleship one foot into the air.

In considering the relative effects of such a collision on the two vessels it is to be remembered that the "New Hampshire" received the blow practically *broadside on*, so that her plating acted merely as a thin membrane for holding together the framing, and except in assisting to transmit the stress to the framing the plating itself could not be expected to contribute any material resistance to the blow. The "Commonwealth," on the contrary, delivered the blow with her knife-like bow armored with its steel stem, and her plating received the impact *edge on*, so to speak, and in the most advantageous way possible to enable the plating not only to transmit the stress to the framing, but also to take its full proportion of such stress.

An examination of the stern of the "New Hampshire" by our representative disclosed the fact that she had withstood the enormous impact remarkably well. One could not desire a better tribute either to the quality of the product of our steel manufacturers or to the careful and efficient inspection of every piece of material entering into the hull of such a vessel by the representatives of the Navy Department, than was given by a view of the tangled and distorted mass of twisted plating and shapes.



Bow of the "Commonwealth," showing how the steel protective deck of the battleship cut deeply into the bow structure

The protective deck of the "New Hampshire," upon which the seaman is standing, is intact. The lighter structure above was torn loose and driven into the ship.

The outside shell plating, ⅝ inch in thickness, from main deck to water line was bent inboard in a wedge-shaped section corresponding somewhat with the shape of the "Commonwealth's" bow. The point of impact at the rail of the main deck had been bodily carried forward a distance of over twenty feet, and, as can be seen from the photograph, shows no sign of cracking or rupture throughout the twenty feet of height between the protective and main deck. The rivets, too, have apparently held well, showing surprisingly few heads snapped off. At the protective deck, 1½ inches thick, which on this vessel comes slightly below her water line, the plating and frames have been sheared off, leaving the flat top of the heavy watertight protective deck intact, and as good as the day it was originally installed. There was apparently no damage whatever below the protective deck, which is only another excellent example of the great advantages to be gained either in warship or merchant construction of a heavy watertight deck at or near the water line. The presence of this deck slightly below the water line and its absolute intactness prevented practically any water at all from entering the ship.

The plating of the gun and berth decks has been considerably buckled and torn, and the four or five after beams and frames on both sides were so badly twisted as to require renewal. On the main deck the plating and beams were badly bent, and the wood deck torn and shattered.

The compartments involved were the extreme after cabin of the commanding officer, the bath and shower room for the wardroom officers, and the after staterooms on each side. In these spaces all fresh and salt water piping, ventilation ducts, steam pipes, electric light fixtures, wiring and conduit, tiling, etc., were completely wrecked, together with a number of fittings, such as airports, gunport shutters, deck stanchions, flagstaff, etc.

Several of the 2-inch nickel-steel plates of armor protecting the after 6-pounder guns were bent through an angle of about 125 degrees, but gave no evidence of cracking, and the authorities expressed the belief that these could be heated, straightened and used again. One heavier 3-inch plate of armor at the water line showed evidence of having been slightly bent in one corner, but no further injury was received by the water-line armor.

There was apparently no damage done to the propellers, shafting or rudder, which can only be considered a piece of very good fortune.

The repairs to the stern, which must be done with the vessel in dock, will probably be executed by cutting off the whole damaged portion above the protective deck by the use of pneumatic chipping hammers, and the oxy-acetylene flame and lifting it bodily off. This portion will then be replaced by a whole new stern, fitted complete in all respects, which will require an expenditure of about $15,000 and six weeks time.

The damage to the "Commonwealth," which it is also estimated will cost about $15,000 to repair, consisted of a broken stem and a very badly crumpled and twisted bow, which will involve the renewal of a large number of her forward plates and frames, and will necessitate docking the vessel. The injury sustained by this vessel shows the great value of efficient collision bulkheads, which held perfectly in this case. The knife-like effect of the armored protective deck of the battleship in shearing the shell plating and forward frames of the "Commonwealth" is plainly visible in the illustration.

The most gratifying thing about the accident, if indeed anything can be said to be gratifying about such an unfortunate occurrence, was the perfect order and discipline observed on both vessels immediately after the collision. In spite of the heavy fog that prevailed, and the fact that, except for those immediately on

(Concluded on page 87.)

Artificial Surf Baths

A Miniature Indoor Ocean

PROBABLY no feature of the International Hygiene Exposition held in Dresden last year attracted more general interest than the Undosa artificial surf bath. The receipts from the sale of bath tickets, and especially of spectators' tickets, were unexpectedly large, amounting sometimes to $450 in a single day. As the cost of operation was only about $40 per day, it is evident that the artificial surf bath may be made a very profitable as well as a very beneficial institution.

The idea of generating waves in still water by alternately submerging and withdrawing solid bodies of appropriate form and dimension, originated with Hofrat Hoeglauer of Munich, who in 1903 obtained a German patent for a wave-producing apparatus, which was subsequently patented in the United States and many other countries. The first experiment in the production of an artificial surf bath by this method was made in 1905 in a concrete basin built in Lake Stamberg.

The bath could be used only in summer, and, although it was very well patronized on clear hot days, it was evident that long periods of fine summer weather would be required in order to pay the operating expenses and provide for amortization and fair interest on the initial outlay.

It was left for the Dresden Hygienic Exposition to demonstrate that artificial surf baths can be made profitable by constructing them in such a manner that they can be used throughout the year in all sorts of weather. The directors of the Exposition had decided that the department of sport would not be complete without a large swimming bath in which swimming races could be conducted. The constructor of the bath, Herr Heckmagel, suggested that it be provided with a removable roof, and also with apparatus for producing artificial surf. This plan was finally adopted after much discussion and with grave financial misgivings, and the result surpassed all expectations. During the five months of its operation the bath was visited by nearly half a million persons and earned about $30,000, which more than covered the cost of construction ($20,000), and the operating expenses (about $7,000). The cost of construction was diminished about one-half by the gratuitous contribution of many parts of the equipment by exhibitors, and the site cost nothing, but it appears probable that a similar enterprise would pay very well in normal conditions. The additional outlay for the wave-producing apparatus would not exceed $7,000.

The mechanical device by which the waves are produced is very simple in principle. It consists essentially of one or more hollow wedge-shaped bodies made of sheet iron, which are rhythmically immersed in and drawn out of the water by appropriate machinery. In situations in which the vertical elevation and depression of the wedges present difficulties the waves may be generated by oscillating vanes, but the operation is always so conducted that the water which rushes in to fill the void produced by the elevation of the wedge or the retraction of the vane passes the point of equilibrium and is heaped up by the return swing of the vane or the immersion of the wedge. The wave-forming action, therefore, is identical in principle with that of a stone thrown into a pond. If the stone falls close to the bank, so that the water can escape in only one direction, the height of the resultant waves is increased.

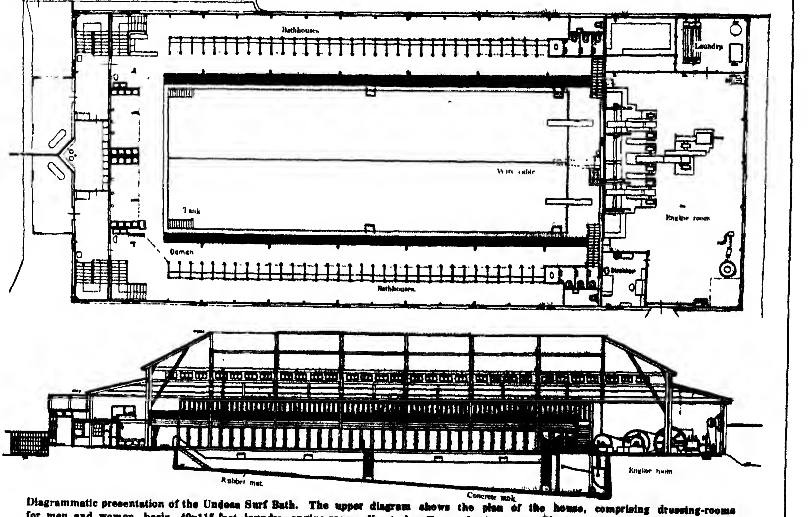
In the experimental plant in Lake Stamberg the waves were generated by three immersion wedges arranged in a straight line, each of which was driven by a separate electric motor, in order to save space. Each motor was coupled directly to a flywheel. When the motor, running without load, had attained the proper speed of rotation, the motor shaft was connected by a worm drive with a horizontal shaft carrying a crank from the end of which the wedge-shaped plunger was suspended. In designing the artificial surf bath at the Dresden Exposition steam was chosen as the motive power in order that the water of the bath and the air of the bathhouse might be heated by the exhaust steam. At first the steam was supplied by the general power house of the Exposition, about 1,000 feet distant, but subsequently a locomotive boiler of 100 horse-power was installed in the bathhouse.

The wave-generating plungers were suspended from cranks attached to a shaft extending across one end of the swimming tank, which was about 40 feet wide and 115 feet long. This shaft could be connected by belt wheels and clutches near its ends, with a counter-shaft at the middle of which was a wheel driven by a belt from the engine shaft. The gearing was constructed to immerse the plungers 18 times per minute when the engine was running at its normal rate of 125 revolutions per minute. The bottom of the basin was inclined in the usual manner, and the plungers were placed at its lower end, where the depth of water was about 7 feet. The waves generated at this end of the basin were more than 3 feet in height, and as they moved toward the other end and reached a point where the depth of water was less than their height they began to comb and break, and thus produced a very good imitation of the surf of a natural sea beach.

The arrangement of the plungers or vanes, and the character of the impulse impressed upon the water, can be varied in divers ways. Where space is limited, for example, a plunger could be attached directly to the piston rod of a vertical engine placed above it, as in one form of steam hammer. Plungers could be operated in the middle of a long basin so as to send waves toward both ends. The two parts of such a basin, divided by the machinery and a screen, could be used as separate baths for men and for women.

The height of the waves is conditioned by the volume of water displaced, and it can be varied within wide limits by varying either the travel of the plungers or the depth of water. For artificial basins the best practical method consists in varying the travel and distributing several plungers across the deep end of the basin. With three plungers constructed to be operated separately a great diversity of wave motion can be produced by using one plunger, two, or all three. If the three plungers, properly distributed, are operated together and synchronously, the whole basin is filled with regular waves of uniform height; while if even one plunger remains idle, the waves generated by the others spread into the calm water in front of it, and thus lose force and height as they approach the farther end. By accelerating or retarding individual plungers it is possible, as observation has shown, to produce a very complex wave pattern resembling that of the open sea.

Practically all of the conditions presented by a natural beach can be reproduced by doing away with the vertical wall at the shallow end of the basin and extending the inclined floor well beyond the water line. The difficult art of swimming in rough water can be practised at one end of the basin, while at the other end bathers can enjoy the breakers, the outrunners of which furnish safe amusement for small children. All of these persons may derive benefit from the massage effected by the moving water.



Diagrammatic presentation of the Undosa Surf Bath. The upper diagram shows the plan of the house, comprising dressing-rooms for men and women, basin, 40x115 feet, laundry, engine-room, director's office and wire rope. The lower shows a longitudinal vertical section of the same, with position of rubber mat, inclined concrete floor, engine-room and canvas roof, opened by rolling up.

The "Hawke"-"Olympic" Collision

To the Editor of the SCIENTIFIC AMERICAN:

Your article in SUPPLEMENT of February 24th, 1912, page 114, suggests that there are some things that pilots and professors do not know or have never reasoned about. For instance, that when a vessel passes swiftly through the water, and that water is deep, *the greater part of the water that refills the hole where the vessel was, comes from below.* If this was not so, almost everyone falling overboard would be struck by the propeller, which we know is not the case. Unless these conditions, it is safe for vessels in smooth water on parallel courses to range alongside one another and sheer off with ease.

Again, when a vessel passes swiftly through shallow water, she *"smells the bottom;"* that is, *the greater part of the water which refills the hole where she was, comes from the sides.* The water under the bow cannot get to the stern quick enough, so it is piled up ahead of her, as we see when large vessels are passing through the Suez canal; the ship's speed is reduced because she is trying to go stern first from the piled-up water ahead to the low-level water astern, and the rudder becomes more or less useless.

Under these conditions, practical experiment will show that safety for two vessels only lies in a *"very wide berth."*

LAW. HARGRAVE.

A Good Roads Suggestion

To the Editor of the SCIENTIFIC AMERICAN.

Regarding permanent roadways, "good roads," the writer would suggest the building of 16-foot or 20-foot Belgium pavement roads or stone block pavements, with 3 feet in depth curbing 4 or 5 inches thick. This roadway to be placed in the middle of the road, and the balance of the road could be graded or built of earth or crushed rock or of such material as found most available. This stone pavement with a 2-foot rough concrete foundation would last for many years and prove to be cheaper in the long run.

The Reproduction of Sound

To the Editor of the SCIENTIFIC AMERICAN:

Your Paris correspondent in a recent issue of your paper entertained your readers with the narrative of a supposedly novel method of reproducing sound, consisting in forcing a current of air through an airpervious sound record. If you will look at U. S. patent No. 908,683, you will see that this principle is my invention and dates back six years or more. I inclose a piece of a record such as I used at that time.

The Gyroscopic Action in Aeroplanes

To the Editor of the SCIENTIFIC AMERICAN:

The theory of the correspondent in the April 20th number of your paper, regarding the tendency of a certain flying machine to turn to the left, seems to agree with that I advanced in the March 9th number, but in the interest of truth I would like to say that we are both probably wrong. The solution given by "Canadian Subscriber" in the March 2d number is undoubtedly the correct one.

Niles, Mich.

Mr. Turnbull on the Center of Pressure in Aeroplanes

To the Editor of the SCIENTIFIC AMERICAN:

In your issue of May 18th, 1912, there is an article describing "The New Eiffel Aerodynamic Laboratory at Auteuil," and in it M. Eiffel is credited with a discovery, concerning the center of pressure of a doubly curved surface, that was really made by Turnbull in 1906.

The paragraph to which I refer in your article states that "M. Eiffel has found, however, that by giving the rear portion of the plane a reverse or upward curve, the movement of the center of pressure is reversed. In other words, when the angle of attack is diminished, the center of pressure travels forward, and only travels backward when the angle of attack is increased. This is a result of great practical importance, as it means that by having planes with a reverse curvature, a considerable degree of inherent longitudinal stability is obtained. For example, if a machine in flight suddenly tends to dive, the diminishing of the angle of attack will cause the center of pressure to move forward, and this will give a stabilizing effect tending to lift the forward part of the plane. On the other hand, if the angle of attack is suddenly increased, the backward movement of the center of pressure will tend to right the machine and not allow it to assume too great an angle."

Now, in an article published in the *Physical Review* in March, 1907 (and reprinted in the SCIENTIFIC AMERICAN SUPPLEMENT of January 30th, 1909) I described the movement of the center of pressure with five different types of planes, and drew most particular attention to the inherent longitudinal stability that could be obtained by the use of the double curvature type (No. IV in my article) having concave front and convex rear portion (on the under side).

In fact, my center of pressure curves, my results and deductions are practically identical to those of Eiffel cited above, and obtained patents in the United States, Great Britain, France, and Canada on the "type IV" surface, on account of its inherent longitudinal stability

While I do not wish to detract from the valuable results Eiffel has given us, concerning many aerodynamical questions, it is only fair to state that, concerning the longitudinal stability of the doubly curved surface, my results antedated those of Eiffel by *fully five years*, as can be very easily verified by consulting the references already given.

W. R. TURNBULL.

A Proposed Solution of the Compulsory License Problem

To the Editor of the SCIENTIFIC AMERICAN.

A number of writers are expressing their disapproval of the compulsory license provision of the patent bill now being considered in Washington.

Could not most of this opposition be appeased if the bill were changed to apply to the purchaser of a patent, and not to the original inventor?

In this way any conflict with the Constitution would be avoided, and the direct object of the authors of the bill just as certainly realized.

The pigeon-holing of patents is not wholly practised for reasons of self-preservation or self-defense, as some would have us believe.

Unquestionably, a vast amount of lawful and beneficial competition is suppressed by this means.

Chicago, Ill. C. W. EISENMANN

[We fear that the suggestion, while good in intention, is impracticable The practice of employing dummy directors for corporations shows how easy it would be to circumvent any such law as that proposed. The inventor would simply be used as a tool by his more powerful assignee.—EDITOR.]

Conserving the Atmosphere

To the Editor of the SCIENTIFIC AMERICAN

While the rapid destruction of our forests and exhaustion of our coal supplies are indeed questions of the uttermost seriousness, I cannot agree with your correspondent, Mr. Thorington Chase (whose letter was published in your issue of May 18th) that the "conservation" of our atmosphere is a matter to cause us the least concern.

True it is that the wonderful increase in the world's industrial activities during the past hundred years, entailing the burning of enormous and rapidly increasing quantities of coal and other fuels, results in throwing off into our atmosphere vast and constantly increasing quantities of carbon dioxide, which, if it were not in some way removed from the air, would in time render human life upon this earth impossible. But just here is where the beautiful balance of nature comes in; for as we increase the burden of carbon dioxide in the atmosphere, we stimulate the growth of plant life, which absorbs the carbon dioxide, "digests" out the carbon, and returns the pure oxygen to the air. In other words, the more carbon dioxide there is in the air, the more rapid and luxuriant will plant growth become, which in turn will return more oxygen to the air. Therefore the only result of artificially increasing the production of carbon dioxide is to stimulate plant growth, and is thus on the whole beneficial to the human race. And further than this, it is not the slowly growing forest trees that are the most efficient purifiers of the atmosphere, but the more rapidly growing annual plants upon which we depend for our food supply.

When your correspondent speaks of the "uncalculated millions" of tons of oxygen which are discarded in slag from our blast furnaces as fixed oxygen, he apparently forgets that any oxygen that goes into the slag does not come from the atmosphere, but from the iron ore itself, where it has already been "fixed" by nature. Practically all our commercial production of iron is from ores which are oxides of iron, containing more fixed oxygen than the resulting slag. Therefore the reduction of such ores tends rather to increase than to decrease the burden of oxygen in the air. True, it comes from the furnace stack as carbon dioxide, but only to be eventually freed from its carbon by plant life.

I would like very much to know upon what information your correspondent bases his statement that "aviators have noticed inexplainable absence of available oxygen in the upper strata of the atmosphere." The presence of an excess of carbon dioxide in the atmosphere could have nothing to do with such a condition, as carbon dioxide is heavier than air, and naturally would lie close to the ground. Of course, the amount of oxygen per cubic yard decreases as we ascend, in the same proportion that the density of the air decreases, but this is surely not "unexplainable."

Philadelphia, Pa. E J D COXE.

Compromise Plan for Upbuilding Our Merchant Marine

To the Editor of the SCIENTIFIC AMERICAN.

Though many views on the subject of the merchant marine have been discussed in the SCIENTIFIC AMERICAN, there is one which I have not seen there, and which I desire to present.

There seem to be three well-defined plans which have been advanced as possible methods of solution of this great economic question. These are ship subsidies, preferential duties, and free ships. Each plan has its merits and demerits, and our problem is to find, if possible, a plan embodying the merits of each system with as few as possible of the defects.

Ship subsidies are distasteful to the American sense of justice, and since subsidies cannot be general, they must constitute more or less of a monopoly. Because of this, and because of the opportunity for graft afforded by direct government assistance to private enterprise, ship subsidies would encounter too much opposition to be applicable.

The chief opposition to preferential duties is, that they would excite similar duties in other countries; but since nearly all governments have some form of public protection already, there should be no reason why America could not do likewise. Another objection is that with preferential duties foreign ships would not be able to compete with the Americans. This is due to Congressman Sulzer's advocacy of a five per cent difference in duties regardless of difference in cost of transportation.

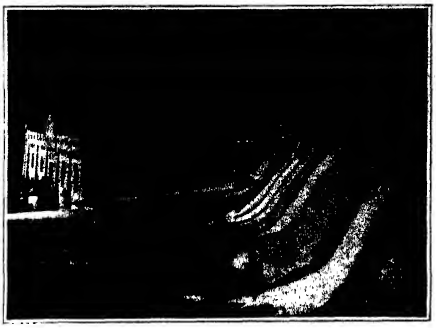
For many years our factories have been protected by a policy of laying such a duty on imported articles that the difference in cost of production at home and abroad is nullified by the tax paid on foreign goods. Under this system our factories have prospered until they are able to do without the tariff. If our merchant marine needs protection, why not protect it in the same way? It is agreed that for various causes, most of them temporary, it costs more to transport goods under the American than under a foreign flag This is the economic cause which has ruined the American merchant marine. To rebuild our merchant marine, we must remove this cause. The best way to do this is to make the difference in duties between goods brought in American and foreign bottoms such that for every commodity and every voyage it will just compensate the difference in cost of transportation. This will enable American vessels to compete with the ships of all other nations in voyages between American and foreign ports. Such a system of preferential duties, regulated by a board similar to the Tariff Board, would place our merchant marine in a position to compete with the world, while yet preserving that healthy competition which is necessary to any enterprise

It has been pointed out that with all our shipyards working to their full capacity, it would take twenty years to construct sufficient vessels to carry our trade Then for a few years some of our ships must be built in foreign yards or transferred from foreign registry Our problem then is to find the most satisfactory method of admitting foreign-built ships to American registry The free-ship plan would admit foreign-built vessels owned by Americans to registry without any stipulation as to condition and with no fees This would force our yards to compete with the oldest and most efficient yards of Europe at a time when they are least able to stand it. Such a method would inevitably lead to the practical annihilation of our shipbuilding industry Manifestly then free ships are impossible Then let us find a method which is satisfactory

It costs less to build a ship abroad than it does at home. This is due to cheaper labor, cheaper materials, and better management. If it costs less to build a ship abroad than it does at home, our shipyards cannot compete on a free and equal basis. Then why not apply those same principles of protection which have been so successful in stimulating our manufacturing industries? Why not lay a tax on the American registration of foreign-built vessels which will just compensate for the difference in cost of production at home and abroad? Under such a system of protection, controlled by the same board which is suggested to regulate our preferential duties, our shipyards would be stimulated by healthful competition without being forced out of business by an economic factor beyond their control This system would automatically cease when the shipyards of America cease to need it—when the cost of production at home and abroad is equalized

With the experience which we have had in protecting our factories, it would seem that the application of the same principles to our maritime problems should at least receive careful consideration. Any action which the Government takes on this most important subject must come as the echo of the thought of the people, and we can have no action until the people have considered the question from all sides.

Bergen, N. Y. W ARNOLD HOSMER.



Lienfoss power station.

Factories at Saaheim.

A Mammoth Norwegian Power Plant

Telemarken's Great Industry

NORWAY has entered the ranks of the countries which are devoted to huge industries. Throughout the country there is evident a feverish ambition and energy toward being up and doing. Great new factories are being built, and Norway's famous old water-falls ("Foss") are being harnessed for commercial use. Largest and most imposing of all, in this connection, are the enterprises which derive their power from the plant at Rjukan,* the immense industrial works which lie between Mosvand and Hitterdalsvand.

In the course of the last year, principally at the initiative of Mr. Eyde, general director, a number of water-power plants have sprung up in Norway. Among these are the plants at Tysse, Bollefoss, Vammafoss, Lienfoss, Svaelgfoss and Rjukanfoss. These plants are to serve electro-technical science and industry, and the harnessing of the waterfalls may be said to mark a turning point in the economic development of the country.

The last three of the above mentioned water-power plants, Svaelgfoss, Lienfoss and Rjukanfoss, are all built exclusively for the manufacturing of saltpeter—Norwegian saltpeter, as it is called, in distinction from Chili saltpeter. Chili, as is well known, has hitherto been the only country from which this absolutely necessary product could be obtained for agricultural fertilizing purposes.

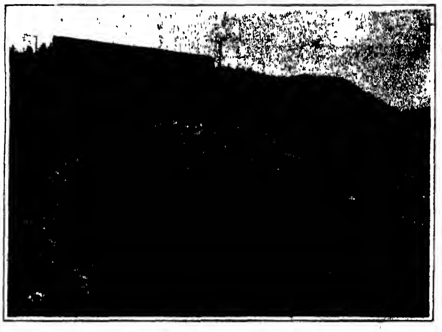
Of the three plants Rjukanfoss is the largest and the most impressive. With its 145,000 horse-power, it is one of the world's great power plants. Not even the plants which are located at Niagara have so powerful and extensive a system. When the other plant, Rjukan No. 2, is completed an additional 125,000 horse-power will be obtained, so that the power utilized here will be 270,000 horse-power, which is more than half of the combined power that once sufficed for all of Norway's industries put together in 1900, viz. 533,758 horse-power.

This is the world-famous Rjukanfoss of Norway, the power of which has thus at last been harnessed. The huge "Kettle" situated under the falls, from which the water rose perpendicularly into the air, and from which the old "foss" sent its powerful bass-voice out over the valley in an everlasting monotonous hum, is now almost entirely dry, and not a sound is to be heard. Where the old mythical Marisit, famous in saga and folklore, almost "hung" down from the side of the mountain, there is now to be found a broad wagon road running into and along it.

In order to supply permanent water-power the year round, the Moswater situated in the mountains has been walled in and dammed up. Not less than 28,250 million cubic feet can here be kept back and collected when the snow thaws in the springtime, and the waters from the mountains rush down toward the valley. In this way the river Maana, which forms the outlet for the waters of Moswater, throughout the entire year can be made to flow along with a velocity equal to 1,660 cubic feet per second, and the power station in this way is enabled to furnish always the same amount of energy to the factory.

Moswater is, without exception, the greatest water reservoir in Europe, and in the entire world it is excelled only by the mighty Assuan dam over the Nile, in Egypt.

About 6.2 miles below Moswater, and 1.9 miles above the old Rjukanfoss, at Skarsfoss, the entrance to the power station Skarsfosdammen is situated. Here commences the 3-mile long tunnel. One huge fall rushes downward, with a number of smaller falls augmenting it in its course, and the tunnel runs along the mountain side slightly leaning inward, until it winds up in an open basin about 3,610 feet wide and 49.2 feet deep, blasted out of the mountain. From this the water is taken and carried through ten conduits about 5 feet in diameter, down to the turbines in the power station called Rjukan Power Plant No. 1—dropping in their course about 950 feet perpendicularly.

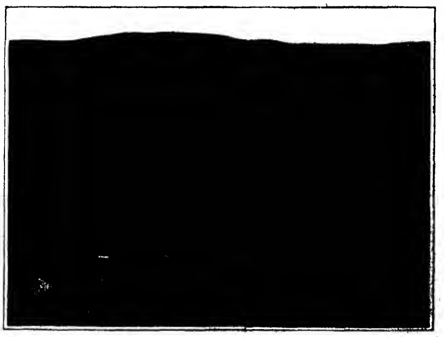


Pipe lines running from reservoir dam 870 feet to power station.

If the machinery in the power station is to be stopped, the penstocks are closed, whereby the water is liberated out over the mountain-side. Nearly 1,640 feet vertically measured, the water falls down before it reaches the river at the bottom of the valley. It is the "new" so-called Rjukanfoss which is thus being artificially created through technical skill and human ingenuity—a fall even more impressive than was the old Rjukanfoss.

From the power station the water is once more led into the tunnel, situated in the mountain-side, and carried about 3 miles downward to the other power plant, Rjukan Power Plant No. 2. However, as long as Rjukan No. 2 is incomplete, the water from Rjukan No. 1 continues to fall 328 feet perpendicularly downward to the river, at the bottom of the valley.

Each of the turbines in the power station represents 14,500 horse-power. This is one of the most gigantic water systems of its kind in the world. The turbines are coupled directly to the generators. It is this machinery which furnishes through conduits to the factory the electrical current which runs them.



Rjukan power station with pipe line.

Between the power station situated at Vemark and the saltpeter factory at Saaheim is about three miles. Above, at the station, not much is to be seen of the five to six thousand people who have moved into the valley; for the service necessary for the plants is comparatively small—only about 40 to 50 men being required.

If, however, we follow the development downward into the narrow valley, we soon encounter at a few miles the new town called Saaheim.

The power conduit in the factory enters it through the "furnace house" so-called. Here the electric furnaces are located, partly erected by Birkeland-Eyde, and partly of German construction. In these furnaces great electric flames burn, and air is forced into them with great velocity.

owing to the electric flame and the high temperature which prevails in the furnace, the elements of which the air is composed are in part forced to combine with one another in a peculiar chemical compound, while the air in its natural state consists only of a mechanical blending of various gases, and where, therefore, each variety of gas exists separately. By the chemical combination of these two elements nitric oxide is produced, which forms the basic principle for the making of nitric acid, and through this, of saltpeter proper. In order to manufacture saltpeter, a big apparatus is, however, required, because the gases which are liberated from the furnace with a temperature of several hundred degrees Centigrade must be cooled and subjected to a prolonged chemical process, before being converted into nitric acid.

The cooling takes place in the following manner: The hot gases are carried through the fireboxes and boilers. The steam which thereby is produced is again utilized as motive power for pumps, locomotives, etc., and for the further manufacturing of the product. The most imposing feature in the entire manufacturing process is, however, the great absorption towers, in which the gases are converted through water into nitric acid. These colossal towers are built of granite, they are ten-cornered, about twenty-three feet across and over sixty-six feet high. Within the tower, which has a floor area of 75,350 square feet and a height of about ninety feet, stand no less than 32 huge granite towers, besides many additional iron towers and machines. The tower proper is so large that the royal palace, which stands in the royal park at Christiania, could be placed within it.

The saltpeter is manufactured by a process through which the nitric acid is led over limestone, which in this way is decomposed. The decomposition is there after saturated with live steam from the above-mentioned coolers, until the complete mass becomes a solid, which thereupon is powdered and packed into barrels ready for shipment.

The factory has its own mechanics' workshop, and, of course, a barrel factory, which last named can produce upward of 6,000 barrels in 24 hours.

On the other side of the river lies the town of Saaheim itself. It has about 5,000 inhabitants, and will, presumably, in the course of a few years, when the other great plant, Rjukan No. 2, has been completed, grow to more than twice its present number of inhabitants. The company has invested heavily in the town, modernizing it in every respect, and it makes throughout a solid and comfortable impression. The houses are for one, two, and four families. Of late "Own Home" houses have been also built, for which the company supplies easy loans to its workmen, engineers, etc. Water pipes are installed throughout in the new houses, also laundry and modern water closets. In the same way modern streets and roads have been built with up-to-date sewers, etc. Electric light is, of course, installed everywhere.

On the same side as the factory, just below it, lies Saaheim railroad station. For shipment of goods to and from the factory the company has built its own electric standard gage railroad, all the way from Notodden and up to the ferry connection, Rollo ferry, so called, over the beautiful Tinn Lake, where the railroad cars are transported across directly on the ferry. The railroad is 28.6 miles long, and the ferry connection over Tinn Lake is about 22 miles. The Tinn Lake is regulated by a dam called Tinnosdammen The Tinn River is dammed up through the magnificent Svaelgfoss, making a large sheet of water, which now is called Kloumannsj Lake. Here lies, directly under the dam, deep down at the old river bottom, the large Svaelgfoss power station, which sends its 40,000 horse-power in a colossal power conduit to Notodden. This plant is comparatively the cheapest in the world of its kind. On the road to Notodden 15,600 horse-power is brought from Lienfoss power station into the same conduit and carried by Tinnfoss down to the factories of Notodden, where saltpeter is also manufactured. At Notodden the product is shipped to the company's huge warehouse and shipping point, Menstad, down by Skienselven. When in the course of a few years—as it is reasonable to presume—the present canal at Skien, Notodden, is widened, the sea-going ships will be able to go straight up to Notodden, and it will, without a doubt, not be long before all the other waterfalls in Telemarken are harnessed for industrial use as well.

In Norway are to be found many dormant natural riches, which, however, hitherto have been considered too poor or of too small a yield to be able to take up the competition with those of a similar nature in other countries. Through the development of electro-technical science of later years, the cheap motive power which the waterfalls of Norway have supplied, will undoubtedly enable her in many directions to take up the competition with the old industrial countries. One must, however, not lose sight of the fact, as is often done, that it is not alone the motive power which plays a dominant and deciding part in the industrial development of a country; other factors have to be reckoned with in the final analysis, among which are shipping facilities and cost, freight, labor conditions, taxes to state and community, etc. These very often are just as important as the first. It is, therefore, of vital importance that the country should endeavor to create for its new industries that are trying to get a permanent foothold there, as good and cheap transportation and similar accommodations and attractive labor conditions as possible Regard must also be had for the people who make their energy part of the enterprises, identifying themselves with the works. If this is done, without a doubt, before long the great plants in Vestfjordsdalen will be followed by others of equal magnitude and as important for the country

Academic Freedom in the Orient

IN wonderful contrast with our most distinguished seats of education, El Azhar, the celebrated university of Cairo the greatest and oldest high school of the Mohammedan world, recently passed the thousandth year of its existence. But unlike our universities, of which the systematic management is always a brilliant phase of their progress, this educational focus of the Orient is also a remarkable example of a really unrestricted, perfect academic freedom. All tribes, peoples and races are represented in the body of students embraced by the university, the number of the last never being the same, but fluctuating between 2,000 and 3,000. This extraordinary alma mater, it must be said, can awaken and retain the affection and loyalty of students with greater ease than any other university, for in very numerous instances the object of the avowed disciples of her particular cycle of sciences who enter the consecrated halls of El Azhar is not merely to attend the lectures, their residence and work between the walls of the university being really a portrayal of their whole lives. Even the barbers have a permanent station in the great vestibule, so that these special students do not need to leave the university in any event.

The heart of the institution is the great court which is splendidly paved Upon it scores of little doors open and loggias and balustrades in great number abound As an architectural entity it is a picturesque oriental masterpiece Those students who with least ease can pay for a small cell in the university incur no expense for the spaces on which they sleep under the roofs of the great open social hall. There is no fee for matriculation, and there is no obligation to pass any examination. Unsubjected to tests and omitting any stated conclusion of study there go forth from El Azhar orators lawyers, physicians and poets, many a man among them having lived for decades within the precincts of this alma mater The teachers and professors receive no salary or other strict compensation, they live on the voluntary dole and presents of their pupils, on the meager price of private instruction, and on the fees they receive for copying old books and manuscripts There is no faculty that calls the professors, no authority that appoints them, every pupil of the university can establish himself after a few years of study independently as a teacher in the halls of El Azhar, begin to lecture and to teach the truth as he knows it or believes he knows it And under such apparent laxity of administration the great university continues an existence that is by no means precarious In the opinion of its staunch friends, of its beneficiaries and of the young men who are waiting to throng to its halls, its authority and importance are more obvious and brilliant and impressive now than ever before

The zeal and loyalty of the students who are leaving it at frequent and irregular intervals are incomparable, and are the source of a later rivalry, in business and profession, of such strangeness, prodigious keenness and persistency as must astound the occidental student who may be quite unfamiliar with oriental customs and who is graduated only in strict accordance with the sheer system that prevails during an arduous curriculum, and is, therefore, much more evenly equipped for frank competition.

Henri Poincaré

The Passing of a Great Mathematician and Philosopher

By J. W. N. Sullivan

THE nineteenth century has been aptly called the age of science. It is not that that century surpassed all others in the magnitude of its discoveries, but that scientific results and scientific methods were then, for the first time, brought home to the minds of the people. The general interest taken in the theory of evolution, consequent on the publication of the "Origin of Species," extended to other branches of science. One great cause which contributed to the general spread of scientific ideas at that time was the part taken by some of the foremost scientific men in presenting their results in a form devoid of technicalities, and in such a way as to be readily understood by the average man. Since that day we have had innumerable popular expositions of every branch of science. Indeed, the writing of popular accounts of scientific discoveries has almost taken rank as a distinct profession. Such writers usually confine their efforts to explaining recent positive discoveries. But of late years something far more interesting than any isolated discovery, however wonderful, has taken place. We are in the midst of a general criticism of scientific procedure, and of the value of scientific results. The scientist has grown uneasy. He is no longer sure of the very foundations on which the whole vast superstructure of modern science is erected. To present these intricate questions, these subtle and far-reaching issues, in a form which renders them readily understood of the average man, requires the hand of a master.

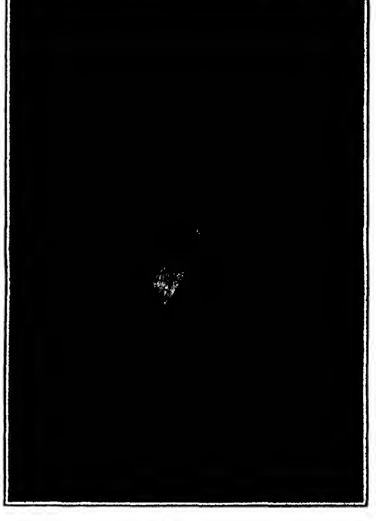
In the domain of mathematics and physics, at any rate, the master appeared. In the late H. Poincaré we had a genius of the first order, a man whose accomplishments in his chosen sphere earned him a foremost place among his contemporaries. By many competent authorities he was considered to have been the greatest mathematician of our day. It would be impossible in the space at our disposal to give an adequate account of Poincaré's work in mathematics, mathematical physics, and dynamical astronomy. We here wish to call attention to his three books, "The Value of Science," "Science and Hypothesis," and "Science and Method."

These works are, in a large measure, critical rather than expository. They contain the profound reflections of their distinguished author on questions of the first importance, and yet are written with such clearness and charm of style that they may be read with pleasure and profit by any ordinary thinking man.

Take, for instance, mathematics, the most impeccable of the sciences. Poincaré sees that its very existence appears paradoxical. We start from definitions and axioms, and deduce consequences which are absolutely necessary results of our premises. We introduce no fresh facts. We make no appeal to experiment. How then can we discover new truths? It would seem that all mathematical reasoning must reduce to a gigantic tautology, and that all the mathematical theorems which fill so many imposing works are simply various ways of saying that A is A.

Poincaré analyzes this paradox and shows that the very essence of mathematical reasoning, and that which alone makes it valuable, is the principle of mathematical induction. This great principle affirms that if a theorem is true of the number 1, and if we can further assert that, being true for the number n, it is true for $n+1$, when we have proved that the theorem is true for all integer numbers. This principle is, in one way, a kind of short cut. It enables us to dispense with the labor of verifying the theorem for every particular case, and is the fundamental characteristic of mathematical reasoning. It alone makes generalization possible.

Again, we all know what great changes have occurred in our way of looking at the fundamental concepts of geometry. Since Lobachevski and Riemann have shown that it is possible to construct perfectly logical and consistent geometries quite unlike Euclid's, the question has arisen in some minds, which geometry is true? For instance, according to Euclid's geometry the three interior angles of a triangle are together equal to two right angles; according to Lobachevski they are less than two right angles, and according to Riemann they are greater than two right angles, and these differences increase with the area of the triangle. Suppose then we effect some astronomical measurements by measuring the angles of the very large triangle formed by the diameter of the earth's orbit and the lines joining its extreme points to a fixed star. If we make our measurements with sufficient accuracy, it would seem that we should be in a position to answer the question, which geometry is true? Poincaré shows us that this is not the case. In making our measurements we have implicitly assumed that light is propagated in straight lines. If we found that the sum of our measured angles was not equal to two right angles, we should not change our geometry, *we should simply conclude that light is not propagated in perfectly straight lines.* We should do this because it would be more *convenient.* This is the key-note to Poincaré's treatment of this subject. It is meaningless to talk about the *truth* of geometric theorems. It is as meaningless as to talk about the *truth* of the metric system. The theorems are necessary consequences of the preliminary hypotheses, and these hypotheses are *arbitrary.* We have selected those we have in preference to others because



HENRI POINCARE

they most nearly and most simply accord with the observed facts *relating to solid bodies* and are, therefore, the most convenient.

We have not space here to give an account of Poincaré's profound remarks on the subjects of space and time, those old bugbears of metaphysics. Suffice it to say that he treats all such questions with unrivaled insight and ability. On the subject-matter of physics proper his views are equally striking and original. He points out that in the accepted theory of matter, the electron theory, Newton's third law, asserting the quality of *action and reaction*, does not hold unless we assume a reaction on the ether which gives the necessary compensation. This fact is of fundamental importance. On analyzing our concept of energy, one of the most important concepts in the whole range of physics, he succeeds in showing that except in a few comparatively simple cases it is very hard to define, and that a general definition simply reduces to saying that in any physical phenomenon there is something which remains constant. This notion of energy, in fact, belongs to a *class of* hypotheses which are distinguished by the fact that they can never be contradicted by experiment. Then there are two classes of hypotheses in science—those which may be submitted to the test of experiment and judged by their behavior under that test, and those which serve us as general controlling principles, but which are outside the range of experiment. Poincaré illustrates this difference very clearly, and an interesting example, taken from biology, has been given by Prof. Royce in his introduction to the American translation of "L'Hypothèse et la Science." This extremely inadequate sketch of the subject matter of Poincaré's popular expositions will, we hope, induce the reader to make the acquaintance of the volumes mentioned. He will find himself amply repaid for his trouble.

Like many other great men, Poincaré manifested his extraordinary powers at a very early age. He was born in Nancy in 1854, the son of a French physician. As a boy he was rather delicate, and disinclined for the society of other boys of his age. He seems to have been a very engaging child and wonderfully intelligent. He was trained first as an engineer, and received his doctorate in mathematics at the age of twenty-five. But he had very early given proof of his extraordinary mathematical powers. It is related that he never took notes of the lectures which he attended, nor did he ever read the copies of the lectures which were distributed among the students. He simply made a mental note of the results given by the professor, and when called upon, could always supply a proof of his own. Like many other people who are in the habit of indulging in intense mental concentration, he did very peculiar things. He was very fond of walking while engaged in thinking out his problems, and had a habit of "fiddling" with something in his hand. This was so well known at the college where he was a student that the professor gave him a bunch of keys to carry as he paced the corridors in meditation. On one occasion he was discovered on one of the principal streets of Paris carrying a large new wicker-work basket in his hand. He suddenly became alive to the fact, and retracing his steps, found that he had unconsciously purloined the basket from a store he had passed some time previously. It is also related that he was once found packing his trunk with the bed-linen of the house where he was a guest under the impression that he was packing his handkerchiefs. The histories of other great mathematicians, such as Gauss and Lagrange, show that intense mental concentration is often accompanied by this peculiar state of oblivion to the external world. In fact, at times, as in the case of Sir Isaac Newton, it has given rise to temporary suspicions regarding their sanity. Poincaré was a well-known figure in Parisian society, and was by no means the retired mathematical recluse of popular imagination. He was a member of the French Academy of Literature, an extraordinary honor for a scientific man, and a member of a great number of scientific societies in various countries. His published works embrace nearly every branch of pure and applied mathematics. His work in dynamical astronomy is of great value. Among other things, he has made contributions to the famous problem of three bodies which are of the first importance. In general function theory he has created a new type of functions. Together with Klein he has applied some of the concepts of the new geometries to the integration of linear differential equations, and he has greatly helped to develop the branch of mathematics known as Analysis Situs.

It is of the greatest interest to know the way in which the mind of a great man works. On this point Poincaré has given us some most illuminating information. There appear to be three stages in the solution of a problem: first, a period of intense mental effort, usually unsuccessful; secondly, a complete mental rest from that particular problem; and thirdly, a sudden revelation of the solution, followed by a period of conscious effort, trying to find the proofs of the answer revealed. We say *conscious* effort, because Poincaré himself believes that the period of apparent mental rest is in reality a period of intense activity, the activity of the subconscious self.

The first period of intense mental activity seems analogous to setting a number of things in motion, which then proceed to form combinations among themselves. The question why the correct combination, and no other, is presented to the conscious mind, does not permit of any very satisfactory answer. But it is significant that the right combination is the one which most appeals to the aesthetic sense of the mathematician, and there is probably a deep relation between the correctness of a theorem and its mathematical beauty.

The seedling soon feeds from the nurse plant.

All the vigor of the older plant is sent into the single shoot of the seedling.

Hurrying Nature

A New Method by Which Trees That Fruited in Eight Years are Made to Bear in Two

By William Atherton Du Puy

A METHOD of hurrying trees to their period of fruiting has been discovered at the Government hothouses at Washington. There the men who juggle with living plants and make them do things of which nature never dreamed, have recently succeeded in diverting the vigor of trees that were large and strong, sending their sap coursing through the veins of spindling seedlings and thereby caused those seedlings to do in two years what ordinarily would have taken eight

Take for example the finger lime of Australia This is an exceedingly rare plant. Three years ago it had not a representative in America. About that time somebody sent three seeds of the finger lime to the Department of Agriculture. These were planted immediately and all grew. Being the seedlings were of the lemon family the scientific growers knew that it would require eight years for the finger lime to come into bearing under normal conditions. Eight years is a long time to wait in an experiment.

At just this period the new method of diverting the vigor of other trees into a seedling was in the course of being established. The process is known as "inarching." One of the finger lime seedlings was inarched upon a vigorous two-year-old lemon tree. All the strength of that tree was diverted into the slender shoot. In two years it had ripened its fruit and the scientists were able to judge of its quality. Further, they were supplied with additional seed with which to start new generations of plants.

This shortening of the fruiting time of plants is of inestimable value to the scientific developer of fruits. The breeding of fruits is one of the most fascinating of the modern sciences, and the results that are just now being obtained read like the romances of conjurers. The greatest stumbling block in the way of the working out of these modern miracles has been the length of time required in producing successive generations of a given plant. It has often happened that a scientist has died before he has accomplished the end for which he has set out. But now the time is to be cut to one fourth, and the probabilities are that results will be, in the coming generation, multiplied a hundred fold.

The inarch is accomplished in this way: The seedling is grown to the age of but three or four weeks. It is a weak little plant of but four or six leaves Nature has stipulated that many years must pass before it comes to maturity, blossoms and bears fruit Under the inarch process this stripling is taken up with a ball of earth about its roots sufficient to maintain its life for a few weeks The whole is transferred to a stalwart vigorous tree of a kindred species This tree may be two or three years old. Its roots are deep. It is supplying sustenance for a top that is a hundred times as large as the seedling.

This is known as the nurse tree. The outer bark is scraped from the side of the nurse tree a foot above the ground. The outer bark is likewise scraped from the seedling. The two wounds are bound together with soft cloth bands. The ball of dirt on the root of the seedling is bound to the side of the nurse tree In two or three weeks the plants have grown together The dirt from the roots of the seedling may be removed. It is now drawing its vigor from the nurse tree. Eventually its roots are cut off smoothly below the point of union The nurse tree has taken the little orphan plant unto itself

But this is not the end. After the union is thoroughly established the plant juggler cuts the top off the great vigorous nurse tree. Then is all the nourishment that was going into its top diverted to the single small stem Then do its roots which have been establishing themselves deep in the soil for years send their vigor into the small seedling The result is such growth as nature never knew The twig has such an abundance of nourishment that it vents some of it in fruiting before its time. And this early fruit is strong and vigorous, showing the utmost possibilities of the tree

There are scores of experiments which the Department of Agriculture has had under way for many years, that have been worked through the slow cycle of generations of plants, but may now be hurried by means of the new method There is the citrange, for instance The citrange is a hybrid fruit It was obtained through that scientific development in fruit breeding that has been going on for the last decade and which has as its basis the cross-fertilization of kindred fruits

The orange, the grapefruit, the lemon, the tangerine, even that ornamental plant known as the mock orange or Japanese orange, all belong to the same family Their relation is so close that they may be cross bred Plants may be cross bred by shaking the pollen from the flower of one into that of the other The process in nature is brought about by bees carrying the pollen from one flower to the other So the scientist, wishing to cross certain varieties, prevents the fertilization of the flowers by the bees by putting paper bags over the given blossoms Then when the time is ripe for the experiment, he removes the bags, shakes the pollen from the flowers of the one plant into those of the other and puts back the paper bags The seeds that result from the fruit from these flowers will be a cross between the two plants used in the experiment They may be planted and the hybrid fruit grown. This is just what has been done between the ordinary orange and the mock orange The mock orange is a cold resistant plant. It will grow as far north as New York The great difficulty with the oranges and citrous fruits in general is that they can grow only in communities not visited by frost So the scientists have sought to cross the cold resistant branch of the orange family with the branch that produces the best fruit and thus secure a plant that will produce a good fruit and will also grow in a cold climate.

Now a hybrid seed so obtained requires, under the methods of unaided nature, the accustomed eight years to bear fruit. A wait of that length of time is necessary before the experimenter knows

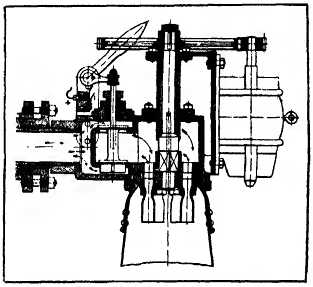
(Concluded on page 86)

A nurse plant with its arms full of seedlings, shortening the fruiting time.

Australian finger lime, the first of its kind ever grown in America, was hurried to fruiting by means of the inarch.

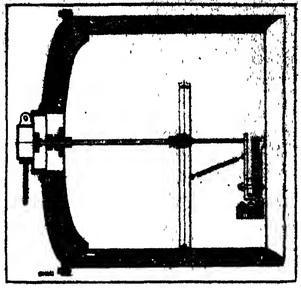
Inventions New and Interesting

Simple Patent Law; Patent Office News; Notes on Trademarks



1.—Vertical section of vibration producer. The disk rotates at a uniform speed so as to give a note of constant pitch. The steam enters the central pivot, passes through the balanced valve and escapes through the expanding nozzles into the small end of the trumpet. The balanced valve is controlled by means of a handle, and the opening and closing of the valve makes and breaks the circuits.

2.—Sir Hiram Maxim, whose latest invention is here described in his own words, believes that it is possible to avoid such disasters as the sinking of the "Titanic" by causing obstructions in the path of a vessel to reflect vibrations produced on the vessel itself. The reflected vibrations are caused to act on sensitive instruments installed on the vessel.



3.—Apparatus for converting the inaudible waves of the echo into audible sounds. Atmospheric vibrations cause a diaphragm to vibrate like a drum-head. In moving it makes and breaks electric circuits and causes bells of various sizes to ring. The pressure of air in front of the diaphragm produces a corresponding pressure inside of the cylinder.

Preventing Collisions at Sea

A Mechanical Application of the Bat's Sixth Sense

By Sir Hiram Maxim

This article is abstracted from a volume published by Cassell & Company, Ltd. For lack of space it has been impossible to present in full the author's ingenious arguments for supposing that a bat really can project vibrations and guide himself by their reflections from surrounding objects under conditions that render the use of the eyes impossible. Moreover, we should like to see the arguments made substantiated by experiments conducted by some competent modern biologist. Sir Hiram's apparatus, however, is based on sound mechanical and physical principles and needs no biological analogue to convince one that it is sound. The reader is referred to Sir Hiram's book for a complete description of the instruments described and of their operation. We can give here only the barest outline.—Editor.

THE wreck of the "Titanic" was a severe and painful shock to us all, many of us lost friends and acquaintances by this dreadful catastrophe. I asked myself: "Has Science reached the end of its tether? Is there no possible means of avoiding such a deplorable loss of life and property? Thousands of ships have been lost by running ashore in a fog, hundreds by collisions with other ships or with icebergs, nearly all resulting in great loss of life and property."

At the end of four hours it occurred to me that ships could be provided with what might be appropriately called a sixth sense, that would detect large objects in their immediate vicinity without the aid of a searchlight.

Much has been said, first and last, by the unscientific of the advantages of a searchlight. Collisions as a rule take place in a fog, and a searchlight is worse than useless even in a light haze, because it illuminates the haze, making all objects beyond absolutely invisible.

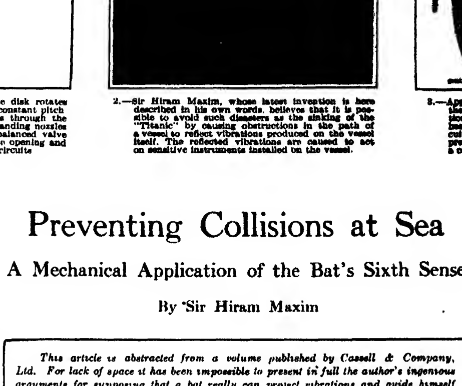
Some have even suggested that a steam whistle or siren might be employed that would periodically give off an extremely powerful sound, that is, a veritable blast, an ear-piercing shriek, and then one is supposed to listen for an echo, it being assumed that if any object should be near, a small portion of the sound would be reflected back to the ship, but this plan when tried proved an absolute failure. The very powerful blast given off by the instrument is extremely painful to the ears and renders them incapable of hearing the very feeble echo which is supposed to occur only a few seconds later. Moreover, sirens or steam whistles of great power are extremely objectionable on board passenger ships, they annoy the passengers and render sleep impossible. It is, therefore, only too evident that nothing in the way of a light or noise producing apparatus could be of any use whatsoever.

Experimenters are fully agreed that the bat possesses what might very properly be called a sixth sense, and that it is able to pursue and capture small insects in the dark under conditions in which eyes would be of little or no use. It is a very curious fact that, notwithstanding that the organ of the sixth sense is the most conspicuous organ possessed by the bat, none of our scientific men have discovered it. It was evidently *too* apparent to be observed, and reminds one of Christian in "Pilgrim's Progress" who was digging in the muck for a crown when the crown in question was directly over his head and very conspicuous. In many cases, the organ that gives the bat the sixth sense is spread all over its face. In the vampire bat the organ is on the tip of the nose; it stands up in the air, and is called the "shield," but in most of the small bats that catch insects on the wing, we find two little leaves, not unlike the wings of the insect that it pursues, standing up just in front of the ears. Others have the sensitive spots located on other parts of the face.

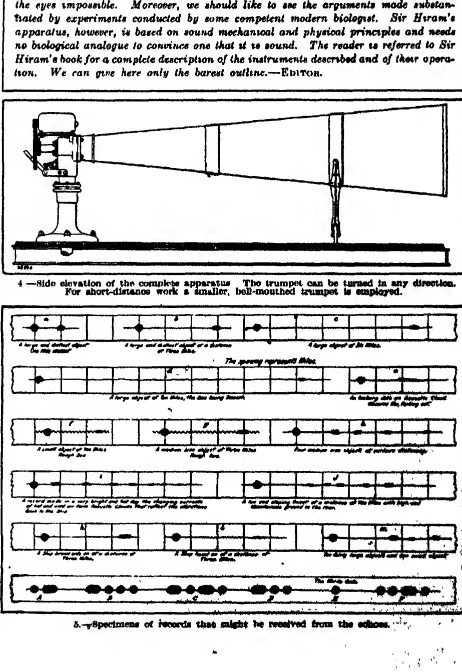
Let us see now what takes place, and what it is that enables the bat to fly about through all manner of obstructions without touching anything, after the manner of a swallow. What enables it to pursue a fly or a beetle in a degree of darkness which renders eyes useless?

In the bats that feed on swiftly flying insects, we find that this small organ is about the shape and size of the wing of the insect on which it feeds. The beat of the insect's wings is communicated to this organ and enables the bat to follow the insect and seize it without seeing it. This is very simple and easily understood, because the insect itself produces certain atmospheric vibrations to which the little leaves in front of the bat's ear respond, but when we come to inanimate things that give off no vibrations of themselves, how does the bat know of their presence? How is it able to judge of their character?

It has already been shown that the wings of the bat are extremely sensitive and very well provided with nerves, and the same is true of the various organs on the face; of course, all of these are intimately connected with one another, and also with the brain of the bat. When a bat flies about in total darkness, the beat of its wings sends out a series of pulsations or waves after the



4.—Side elevation of the complete apparatus. The trumpet can be turned in any direction. For short-distance work a smaller, bell-mouthed trumpet is employed.



5.—Specimens of records that might be received from the echoes.

[illegible] waves, but of too low a [illegible] to be considered as sound. These waves strike against all surrounding [illegible], and, like sound or light, are reflected back to their source of origin. The wings send out the vibrations or impulses and they are reflected back and received by the sensitive organs which form a part of the face of the bat. The extremely delicate nature of the bat's wings, together with the sensitiveness of its organ of the sixth sense, enables it to judge the distance to any object by the lapse of time between the sending out and the receiving of the waves, because it takes some time, some fractional part of a second, for a wave to travel from the bat's wings to the object and return to the bat's face.

We know that this is the mechanism that gives to the bat what is practically a sixth sense. We know it must be true because it cannot be otherwise. That the bat possesses this power is completely beyond dispute, and this is the only way that it can be accomplished. But all bats do not possess this organ; the fruit-eating bats that do not fly about in total darkness have large eyes and never possess this organ, although in some cases we find the rudimentary remains of the organ which they have inherited from their early ancestors, the same as we have inherited the Darwin tip.

The energy employed by the bat is certainly not more than one-thousandth part of a horse-power, but it serves the bat's purpose perfectly well.

Suppose, now, that we construct an apparatus that will produce atmospheric vibrations of about the same frequency as those produced by the bat, but instead of using the infinitesimal amount of energy employed by the bat, we use two or three hundred horse-power—that is, we send out waves that have an amplitude and energy at least three hundred thousand times as great as those sent out by the bat. These vibrations, although of great energy, will not be audible to our ears, but they will shake up and agitate light objects for a considerable distance, and will travel at least twenty miles, so that they could be received and recorded by a suitable apparatus at that distance, and would be able to travel at least five miles and send back to the ship a reflected echo that would be strong enough to be detected.

The quantity of steam required would not be very great, because the valve would not be opened very often, and when open would not remain open more than a second at a time; therefore, the total amount of steam required while signaling was actually going on would certainly not exceed ten horse-power.

The apparatus could also be used for communicating with other ships by giving off long and short blasts representing the dots and dashes of the Morse system.

In providing a ship with a sixth sense, we have to consider three distinct devices. one for producing and sending out the necessary waves, one for receiving the reflected waves and making them audible by ringing bells, and another apparatus for recording the amplitude of the waves.

For producing the vibrations of waves, I prefer to use a modified form of a siren, the disk being rotated at a suitable speed by a motor of some kind, preferably an electric motor. I prefer to use a very high pressure of steam, to have all the parts large and strong, and to produce about fourteen or fifteen vibrations per second These will not come within the range of the human ear, consequently they cannot be considered as sound, and as they are of great amplitude and power they are able to travel over great distances, and when they come in contact with a body, the waves are reflected back to the ship in the same manner that sound would be reflected back, but this echo would not be audible to the human ear. I, therefore, provide an apparatus which might be considered as an artificial ear. It is provided with a large diaphragm tightly drawn over a drum-shaped cylinder, and so arranged that the atmospheric pressure is always the same on both sides, [illegible] of any air blast. It is, [illegible] able to vibrate freely in response to the waves of the echo, and its vibrations are made to open and close certain electrical circuits which ring a series of bells of various sizes. If, for example, the object is very small or at a very great distance from the ship, a very small bell rings, while a large object at a distance of two miles would ring a larger bell, and a very large object a still larger bell. This apparatus gives an audible notice if anything is ahead of the ship.

The other apparatus is similar, but instead of ringing a bell it produces a diagram of the disturbances in the air—that is, when there is no noise except that due to the action of the ship or the sea waves, a wavy line is produced; but whenever the vibrations sent out by the vibrator strike an object and return, the wavy line on the paper becomes very much increased in amplitude so as to be easily observed, and the distance that the object is from the ship can be measured by the length of the paper strip between the giving off of the vibrations and the receiving of the echo; therefore, the distance can be determined with a considerable degree of nicety, and the size of the object may be determined by the amplitude of the waves that return.

Very extensive experiments were conducted about forty years ago by Prof Tyndall at the South Foreland. He found that a deep note emitted by a powerful siren traveled a very long distance, and he was rather surprised at the volume of sound that was reflected back from a ship At that time it was generally supposed that snow, rain, and fog were very unfavorable to the travel of sound, but in his experiments he found that such was not the case. The most unfavorable weather for sound is when the sun is shining brightly and when the air is optically perfectly clear. Under these conditions, we have heated air rising up from the earth, and cooler air descending; this produces a kind of a glimmer in which it is very difficult to sight a gun at long range with any degree of exactness. but my apparatus would not be needed in this kind of weather.

It is well known that the air around a large iceberg is extremely cold—in fact, so cold that certain scientific men have thought that it might be possible to detect the presence of icebergs by the use of a delicate thermometer; but the cold air does not extend far enough around the iceberg to make this practical. Cold air, however, lends itself admirably to the use of my apparatus, because the air itself about the iceberg, being of a different density from the surrounding air, acts as a reflector returning the vibrations to the ship.

In Prof. Tyndall's experiments I find the following:

"In the experiments at the South Foreland, not only was it proved that the acoustic clouds stopped the sound, but that the sounds which had been refused transmission were sent back by reflection."

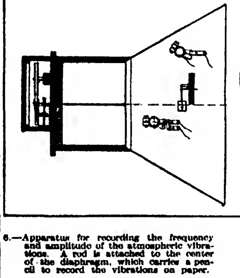
The apparatus for producing the atmospheric vibrations should be placed well forward on the main deck or in any other position where it can be turned about from port to starboard. It should be very firmly secured to the deck, and connected with a high-pressure boiler by a three-inch pipe. A straightway valve should be placed in the pipe near the boiler, and means should be taken to prevent accumulation of water in the pipe leading to the apparatus.

If the sea were perfectly clear, the blasts sent out would be recorded at the very instant of their production, but no echo would be returned other than that due to the waves of the sea, which would produce a zigzag line of small amplitude; but if there should happen to be an object of any considerable size at a distance no greater than two or three miles, the zigzag line on the paper would be changed, the amplitude of the waves would be greater and would be very noticeable. To make sure, the blasts could be repeated several times; and then, if the result should be always the same, it would indicate the presence of some object, and the length of paper between the primary blast and the echo would indicate the distance that the object was from the ship. It might be so arranged that one inch of paper represented a mile.

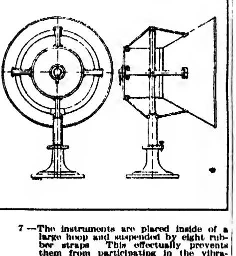
The receiving instruments can be placed anywhere on the ship where they can be turned in the same direction that the siren is turned, and there may be as many of them as desirable.

Of course, there are vastly more accidents caused by running ashore than by collisions at sea, and it does not require a very bold sea front to produce a very strong echo. For example, in approaching the coast of Ireland, the echo would be sufficiently strong to show itself over a distance of at least ten miles

To many it will doubtless appear very difficult, even on the verge of the impossible, to reveal the presence of objects at sea by simply sending out atmospheric vibrations and receiving the echo of the same. One might ask, how can it be possible to judge of the size, distance, and character of the object by the echo? If, however, we make a careful study of the matter, we shall find, if we send out a powerful blast of sound like a deep musical note, that it will travel a long distance, and if it strikes any object of considerable size, it will send back a reflection or echo. Sound is nothing more nor less than atmospheric vibrations. If there are less than sixteen vibrations in a second of time, they are not audible to our ears; we do not hear them, although we may feel them. They may be of great power and able to travel a long distance, and if they should happen to strike any object they send back an echo which, although completely inaudible to our ears, is sufficient to record itself by suitable apparatus, and the record thus made will give us a fair idea of the object struck. It will indicate its size and shape with a fair degree of accuracy; it will indicate its direction from the ship, and will also show its distance with great accuracy. It will distinguish a ship from an iceberg, will show whether the object is stationary or moving, and if moving, the direction and velocity of such movement.



6.—Apparatus for recording the frequency and amplitude of the atmospheric vibrations. A rod is attached to the center of the diaphragm, which carries a pencil to record the vibrations on paper.



7.—The instruments are placed inside of a large hoop and suspended by eight rubber straps This effectually prevents them from participating in the vibrations of a high-powered ship

The Trade-mark as a Business Asset

By W. E. Woodward

[THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer, that it is a symbol of good will, a tangible asset with a determinable money value; that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent

The following is the third of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

The Federal Trade-mark Law.—III.

(Continued from page 62, July 20th, 1912.)

The right to register trade-marks is limited to individuals and corporations.

Under the United States law an association cannot possess a trade-mark, as *exclusive ownership* and *specific origin* are essential attributes of validity

The letters "A-A. L.," meaning Anti-Adulteration League, were refused registration as a trade-mark for flour on the ground that the mark did not represent origin, but membership in an association The applicant was a voluntary association of flour manufacturers. It was held that an association cannot be the "owner" of a trade-mark within the meaning of the statute.

Some States have enacted laws prohibiting the unauthorized use of the labels of trade-unions and similar associations The laws are not trade-mark statutes They are based on the broader principle of unfair business competition.

It is the general opinion, we believe, of trade-mark authorities that the lack of provision in our law for association trade-marks is a defect that should be remedied as soon as possible. It is a noteworthy fact that most of the other great nations recognize association marks.

An interesting example of an association trade-mark is that of the Irish Industrial Development Association. This association has a membership of about five hundred Irish manufacturers. Its use indicates that the merchandise to which it is affixed is of Irish manufacture, in other words, it is indicative of geographical origin. The Irish trade-mark has been registered in Great Britain under the British Trade-mark Act of 1905.

An American of the name of D. B. Barrett attempted to register this mark in the United States Patent Office under his own name. This fact came to the attention of the Irish Industrial Development Association and some correspondence relating to the matter passed between Mr. John Redmond, the leader of the Irish National party in Parliament, and President Taft. As the law now stands, this Irish trade-mark cannot obtain in the United States the protection that registration might give.

Within the last few years several American communities have adopted trade-marks, or labels.

There is a genuine need for an amendment to the law that would give this class of marks the right of registration.

A provision of the Act of 1905 legalized all trade-marks that had been in exclusive use by the applicant for ten years prior to the passage of the act, and this provision applies even to trade-marks of ten years' standing that, because of their character, could not be registered under

the act. The wording of the act dealing with this subject is as follows:

"Nothing herein shall prevent the registration of any mark used by the applicant or his predecessors, or by those from whom title to the trade-mark is derived, in commerce with foreign nations or among the several States, or with the Indian tribes, which was in actual and exclusive use as a trade-mark of the applicant or his predecessors from whom he derived title for ten years next preceding the passage of this act."

A manufacturer cannot register a trade-mark and file it away with the intention of using it at some future time. A condition of validity is that the mark must not only belong to the applicant, but must be "used by him in lawful trade." An intention to use a mark is not sufficient. The use in trade must antedate the application for registration. The letter of the law is complied with if a single package of the goods with the trade-mark affixed is exposed for sale.

Those who intend to adopt trade-marks should keep in mind that the use of a trade-mark is limited strictly to one class of merchandise, which must be the class for which it has been registered.

An applicant for registration must specify not only the general class of merchandise in connection with which he intends to use his trade-mark, but must state also specifically the articles in that class upon which he has used the trade-mark he seeks to register.

For instance, a manufacturer who might apply for the registration of "Pendennis," as a trade-mark for smoking tobacco—to select a word at random—would find that it would not be satisfactory to the Patent Office to state in his application that the mark was being used in connection with Class 17—"Tobacco Products." He would be required to state that his mark was being used on "smoking tobacco." After registration had been granted the Patent Office would not register another "Pendennis" trade-mark in that class of merchandise to be used on cigars, for instance, for another applicant. Nor would the first registrant be obliged to apply for a new registration if he should desire to extend the use of his trade-mark to cigars, or chewing tobacco, or any other tobacco product. The law would protect him in the use of the mark for all articles of that class, but the rules of the Patent Office require applicants to give full particulars not only as to class of merchandise but the specific articles on which the mark has been used.

A result of the principle of trade-mark practice which limits the use of a mark to one class of merchandise is to be seen in the same name being used as registered mark for unrelated articles.

The name "Pompeian," for instance, is used as a trade-mark for a face cream and also for wire netting for window screens; "Republic" is used for automobile tires as well as several other articles in different classes, "Packard" for pianos and automobiles, and there is an "Ideal" hair-brush and an "Ideal" fountain pen.

The law directs that the owner of a registered trade-mark affix, print or impress upon such trade-mark wherever it is used, or in close enough proximity to it to be easily seen, the words: "Registered in U. S. Patent Office," or the shorter abbreviated form, viz., "Reg. U. S. Patent Off." The trade-mark of Baker's cocoa—the Baker chocolate girl—shows how this should be done.

If this notification is not used in connection with the trade-mark, the owner of the mark, in infringement proceedings against an unauthorized user, cannot collect damages unless he can prove that he gave the other party formal notice, and that the unauthorized use of the mark was continued after the notice.

A trade-mark is not merely an advertising symbol. It is an essential of trade-mark validity that the mark be affixed to the goods. A device, or word, or phrase, or picture that is used only in circulars, advertisements, or on signs or letter-heads is not a trade-mark and cannot be protected under the trade-mark laws. (It should be stated here that the unauthorized use by another than the owner of such a device or wording may sometimes be prosecuted under the common law—the law of unfair business competition.)

A trade-mark may be printed, pasted, written, stamped, stenciled, branded, sewed or woven upon the article with which it is used. In cases where it is not practicable to affix the mark upon the merchandise itself it must be affixed to the container.

RULES OF THE PATENT OFFICE.

We have not the space here to go into a detailed description of the procedure of the Patent Office in considering trade-mark applications. This procedure, especially in cases where there is some doubt as to the validity of the mark, is highly complicated, and can be followed successfully only by an attorney experienced in trade-mark practice.

The rules of the Patent Office require applications for registration of trade-marks to be made in a certain conventional form. A drawing of the mark, of a certain specified size, must be submitted with the application. Proofs of the mark, as actually used, must also be forwarded as exhibits in the case.

If, on preliminary examination, the mark appears to be entitled to registration, a reproduction of it is printed at least once in the *Official Gazette* of the Patent Office. This publication must be at least thirty days prior to the date of registration.

The purpose of the publication of the mark in the *Official Gazette* is to allow opposition from any one who thinks its registration would conflict with his rights. Opposing an application is technically called an "opposition." An opposition serves to delay registration until the examiner in charge of interference considers the evidence submitted.

Under certain conditions, rejected applications may, on appeal, be taken up to the Commissioner of Patents.

The number of rejected applications is very large. Under the law of 1905 the total number of applications up to May, 1912, was 62,500.

The total number of registrations under the law is around 42,000. This means that more than 20,000 applications have been rejected in seven years. In other words, about two out of every three applications pass the gauntlet of Patent Office scrutiny, interference and opposition, and are registered.

Many of the defective applications fail because of a lack of competent advice in devising the proposed trade-marks, as well as because of inexperience in prosecuting the applications.

(To be continued.)

Notes for Inventors

Wanted: A Collar Fastening Improvement.—Have you ever tugged at the tab of one of the modern high turn-down collars and fretted yourself into a perspiration before finally getting it fastened? If so, you will realize there is a field for an improvement either in the collar itself to make the fastening easier, or in the collar button, or a substitute for such button which will enable the convenient fastening of the collar and securely hold it when once fastened. Attempts have been made by at least one collar-maker to obviate the necessity of buttoning a collar.

A Device That Loads and Unloads Motor Trucks.—There is considerable activity at the present time in devices for loading and unloading motor trucks through the aid of removable bodies which may be loaded and then applied to the truck. Ralph L. Morgan of Worcester, Mass., has secured a patent, No. 1,030,320, for a motor truck apparatus in which the bed of the truck inclines or curves downwardly at one end so it may readily adjust under a body suitably supported at the desired elevation and a platform is provided having a slip for supporting the crate or body, the slip being so formed that the truck may be run into it and the bed of the truck being slightly higher than the top of the slip so that the truck with the crate upon it may be run into the slip and the crate will be supported on the truck over the slip. Then when the crate or body is fastened at its rear end by a chain or the like, the truck may run out below the crate and the latter be left upon the slip.

Women Inventors.—Voltaire wrote that there are learned women just as there are women warriors; but they are seldom or never inventors. It is not clear whether he intended to exclude from the class of inventors, women generally or only "very learned" women. Certainly women have invented in many fields and it is not seen how learning can decrease their ability in such direction, for another writer tells us that invention is activity of mind and is a sharpening of the spiritual sight, to discern hidden aptitudes. Certainly this spiritual sight should not be dimmed by learning.

Legal Notes

A Trade-mark Ruling.—In the case of Burton Medicine Company v. United Drug Company, Assistant Commissioner Tennant has held that where an opposition to the registration of a trademark is filed by a registrant, a cross bill asking for the cancellation of the opposer's registration will not be admitted.

The Case of a Foreign Trade-mark Applicant.—In the trade-mark case of Ross & Brothers v. The Louis Bergdoll Company v. The Greenway Brewing Company, Assistant-Commissioner Billings has held:

"Where a foreigner applies for registration for a trade-mark subsequent to the registration by a citizen of this country of the same mark, that in order to be entitled to an interference with such registration the foreign applicant must make a *prima facie* showing of use in this country."

A Welsbach Incandescent Filament Decision.—The Court of Appeals of the District of Columbia has affirmed the decision of the Commissioner of Patents holding certain claims in a Welsbach application unpatentable in view of the prior art. The filament presented in the application comprised a stable electrically conducting mixture of osmium and one of the described oxides, and the Court, in affirming the decision of the Commissioner, said that other references to prior patents were given, but it thought that the Edison patent furnished a complete anticipation of the claims involved.

The Supreme Court and Improvements.—History shows that the Supreme Court has followed invention and improvements even in its decisions of constitutional questions. While telegraphy was unknown at the time the Constitution was written and the word itself was not in existence, the Supreme Court brought the term word within the meaning or within the scope of "commerce" as used in the Constitution and Chief Justice Waite thus explained the extension of the power:

"The powers thus granted are not confined to the instrumentalities of commerce . . . known or in use when the Constitution was adopted, but they keep pace with the progress of the country, and adapt themselves to the new developments of time and circumstances. They extend from the horse with its rider to the stage coach, from the sailing vessel to the steamboat, from the coach and the steamboat to the railroad, and from the railroad to the telegraph, as these agencies are successively brought into use to meet the demands of increasing population and wealth."

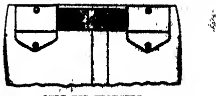
Delay of Application After Reduction to Practice.—In Walker v. Lederer, Mr. Commissioner Moore has decided that "Where W. reduced the invention to practice prior to the earliest date of invention claimed by L., that W. did not forfeit his right to a patent in favor of L. by delay in filing his application where there was no suppression or concealment of the invention." In the course of his decision, the Commissioner says that no case has been cited and he knew of none where a patent had been refused or held invalid solely on the ground of delay in filing the application for patent after a reduction to practice by the inventor and he distinguished from cases where abandonment either intentional or constructive had been established.

RECENTLY PATENTED INVENTIONS

These columns are open to all patentees. The notices are inserted by special arrangement with the inventors. Terms on application to the Advertising Department of the Scientific American.

Pertaining to Apparel.

BELT.—T. Herskowitz, 944 Union Ave., Bronx, N. Y., N. Y. This invention provides a resilient belt for trousers mounted upon the waist-band thereof to maintain an approximately constant pressure on the person of the wearer while expanding to accommodate the movement of the person; provides resilient



BELT FOR TROUSERS.

means for the belt to increase the period of its service; and provides guide members for the belt, said members being attached to the trousers. The advantage in the use of the belt is that the waistband of the garment is held in its correct position upon the wearer's body under all normal conditions. The engraving shows a front view of a fragment of trousers provided with a belt and pocket structure.

Pertaining to Aviation.

AERIAL PROPELLER.—H. L. Elliott, 222 P. O. Building, Kansas City, Mo. The invention is an improvement in so-called screw propellers whose blades are rotatable on their axes in order that they may be set at different transverse angles relative to the plane of rotation of the propeller as a whole, whereby the pitch or lead of the blades may be varied to effect propulsion at different angles.

STABILITY DEVICE.—F. Nyilas, 130 W. 52d St., Manhattan, N. Y., N. Y. This device is more particularly adapted to be applied to aeroplanes. The invention lowers the center of gravity below the center of buoyancy of the floating body. It maintains center of gravity in stationary position with reference to center of buoyancy, irrespective of any force which might tend to change this relation. It will lower the center of gravity during flight and means provide that the device may be moved up parallel with the aeroplane during landing, to economize storage space.

Of General Interest.

PROPELLER.—A. Cardona de los Rios, care of La Alemana Lamparena Electrica, Monte 211 Havana, Cuba. This invention relates more particularly to a propeller comprising an elongated, tapered hub, and an elongated, tapered screw blade, of varying radius, for purposes of propulsion in connection with marine vessels, aeroplanes, etc., which provides means by which negative slip may be minimised.

CIGAR BOX.—J. J. Planco, care of Ruy Suare & Co., 422 E. 53d St., Manhattan, N. Y. This invention relates to a cigar box, and the object is to provide a cigar box in which cigars of peculiar configuration may be packed in position separate from one another so as to prevent injury to the same. Means provide that the cigars are so arranged that they may be readily withdrawn.

Hardware and Tools.

MAGAZINE HAMMER.—O. J. A. Smith, Piedmont, Mo. The purpose of this invention is to provide an improved hammer which is simple and durable in construction, easily manipulated with one hand and arranged for quickly discharging nails, tacks or like fast-

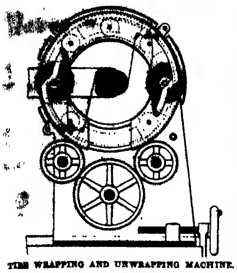
MAGAZINE HAMMER.

eners one by one, for setting the discharged fastener at the desired place on the object into which the fastener is to be driven, and allowing driving the fastener home without requiring the operator to touch or handle the fastener, and leaving one hand free for manipulating the object. The engraving shows a sectional side elevation of the hammer. The inventor's address is care of C. W. Chandler, Greenville, Mo.

ROUTER PLANE.—B. Arlos, 1212 E. 108th St., Cleveland, Ohio. This invention provides a router plane stock with supplemental cutters and routers, the same being placed opposite one another in vertical position and adapted for lateral adjustment as required to cut grooves of different widths. These attachments are located in front of the ordinary router bit, which may be then used to cut and clean out the wood between smaller grooves made by the two attachments when adjusted greater or less distance apart.

[illegible]—J. L. Ashworth, [illegible] Tenn. An object here is [illegible] a device which may be used as a [illegible] a woven wire or a bare-wire stretch[illegible] and which while effectually accomplishing the purpose for which it is intended is simple, and is, therefore, not liable to get out of order.

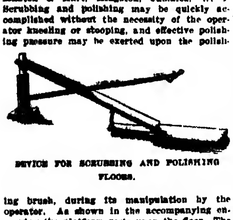
TIRE WRAPPING AND UNWRAPPING MACHINE.—J. W. Throff, care of W. R. Thropp, 2 Stake St., Trenton, N. J. The driving mechanism operates to rotate the tire about its axis at even rate of speed, to secure even winding; a pressure for tire and containing molds is arranged to be imposed on the tire and molds by the driving mechanism, to avoid any friction due to tire movement; driv-



TIRE WRAPPING AND UNWRAPPING MACHINE.

ing mechanism for the shuttle provides for avoiding the need of a filler for gap in the shuttle; a shuttle carries a plurality of bobbins and takes wrapper supply therefor; means provide for removing or renewing the bobbins and supply for the shuttle; also for controlling the speed of the machine, to increase, diminish or reverse the operation thereof, and means to unwind wrappers from the tire and reverse direction of the wrapping. The engraving shows a vertical section of the invention.

APPARATUS FOR SCRUBBING AND POLISHING FLOORS.—F. A. McKay, care of Manton & Hart, Kingston, Jamaica, W. I. Scrubbing and polishing may be quickly accomplished without the necessity of the operator kneeling or stooping, and effective polishing pressure may be exerted upon the polish-



DEVICE FOR SCRUBBING AND POLISHING FLOORS.

ing brush, during its manipulation by the operator. As shown in the accompanying engraving the platform rests upon the floor. The rib being in direct contact with the floor, the operator places his right foot thereon, grasps the handle bar and moves the operating lever back and forth, as shown in dotted lines, thus imparting reciprocating movement to the brush. The device may be moved from right to left as desired to change the point of operation of the brush.

Prime Movers and Their Accessories.

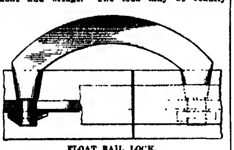
ATTACHMENT FOR OIL WELL APPARATUS.—J. W. Leonard and H. E. Brown, care of G. L. Roberts, 215 Water St., Pittsburgh, Pa. This invention relates to clutches to be applied to machinery adapted to be driven by internal combustion engines. The apparatus may be quickly adjusted to the shaft of a steam engine, the cylinder of which has been replaced by one of the internal combustion type, with the bearing of the extended shaft on which the clutch is mounted, held in rigid relationship to the engine cylinder on a pivoted support to prevent fracture of shaft by the working of the engine on its bed, relatively to the bearing.

Railways and Their Accessories.

TRAIN STOPPING MECHANISM FOR BLOCK SIGNALING SYSTEMS.—M. Conrad, 114 E. Maumee St., Adrian, Mich. This device is for use on trains whose movements are controlled by electric block signaling systems. An object of the invention is to provide means by which the on-coming train may be automatically stopped if the block is not clear.

BLOCK SIGNALING SYSTEM AND SAFETY APPARATUS.—M. Conrad, 114 E. Maumee St., Adrian, Mich. This invention relates to block signaling systems adapted for use on steam or electric roads and designed to be entirely automatic in operation for preventing [illegible] or rear-end collisions on single [illegible] or accidents at crossings and switches, [illegible] dispensing with the usual telegraph [illegible] block offices with their operators and [illegible] and dispensing also with the [illegible].

FLOAT RAIL LOCK.—G. W. Clemmons, 82 Bloomfield St., Hoboken, N. J. This invention relates to a means for locking a car float to a floating bridge. It provides a lock which will maintain the tracks on the float and the tracks on the bridge in alignment, but will, at the same time, permit a slight play between float and bridge. The lock may be readily



FLOAT RAIL LOCK.

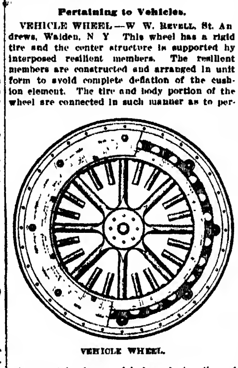
affixed to the rails on bridge or wharf and quickly attached to the rails on a car float. These objects are attained by pivoting a yoke to a rail or bridge or wharf, which yoke has its free opposite end adapted to engage an elongated slot in a correspondingly aligned rail on the float. The engraving shows a plan view looking down upon adjacent meeting ends of contacting rails.

Pertaining to Recreation.

WATER CAROUSEL.—A. C. Bail, 436 E 188th St., Bronx, N. Y. More particularly this invention involves an amusement device made up of a suitable basin in which a number of receptacles, such as tubs, are suitably positioned, means being provided whereby these receptacles may be moved around the basin, a turning movement being imparted to them at the same time.

Pertaining to Vehicles.

VEHICLE WHEEL.—W. W. Revell, St. Andrews, Walden, N. Y. This wheel has a rigid tire and the center structure is supported by interposed resilient members. The resilient members are constructed and arranged in unit form to avoid complete deflation of the cushion element. The tire and body portion of the wheel are connected in such manner as to per-



VEHICLE WHEEL.

mit a certain degree of independent action of the tire and body portion, and to correctly limit the same. The tire construction prevents skidding. The invention provides a tire constructed from relatively thin strips of non-resilient material having disposed therein rings constructed of suitable wire fabric. A side view of the wheel is illustrated herewith.

WHEEL CONSTRUCTION.—H. W. Sanford, care of Sanford Iron Works, Knoxville, Tenn. The object here is the provision of means for preventing wear on the hub and bearing sleeve of wheel mountings, wherein the wheel is journaled on the axle. All end thrust of the wheel pushing inwardly is received by the interchangeable blocks or washers at the center of the axle, thus reducing wear and friction to a minimum.

Note.—Copies of any of these patents will be furnished by the Scientific American for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

Notes and Queries.

Kindly keep your queries on separate sheets of paper when corresponding about such matters as patents subscriptions, books, etc. This will greatly facilitate answering your questions, as in many cases they have to be referred to experts. The full name and address should be given on every sheet. No attention will be paid to unsigned queries. Full hints to correspondents are printed from time to time and will be mailed on request.

(12662) G. L. M. asks. A friend of mine claims that the recoil of a gun does not commence until after the projectile has left the muzzle of the gun, admitting that if the gun were to be infinitely long, there would be no recoil. Is this true? A. The recoil of a gun begins when the bullet begins to move in the gun. Newton's "Third Law of Motion" is applicable to this case: "To every action there is an equal and opposite reaction." There can be no motion of the gun backward till the bullet begins to move in the opposite direction. There is another way to look at it. If the charge of powder were exploded in a chamber strong enough to hold the pressure of the gases, there would be no motion produced by the powder, and no motion of the chamber in any direction. The recoil is due to the fact that the gun has the same quantity of motion backward that the bullet has forward. If the bullet had the same weight as the gun, the gun would move backward with the same velocity as the bullet moves forward, and would strike the same blow as the bullet. It is the motion of the bullet which produces the recoil of the gun. The force of the powder acts in the same manner in every direction. The sides of the gun barrel resist this pressure and prevent motion sidewise. The bullet, if it does not stick, moves. The pressure of the gases is the same forward and backward, and this force is applied to the bullet forward and to the gun backward. Each has the same quantity of motion, or momentum as it is termed.

(12663) J. H. I. writes: I have heard that copper or zinc filings thrown in a fire will reduce the soot in stove and chimney to a fine white powder, obviating necessity of cleaning. A preparation to accomplish this result was once on the market. I shall be glad if you can inform me if you know of the preparation. A. Two receipts for chimney cleaners are given in "Scientific American Cyclopedia of Formulas." First, make a hot fire, then put the compound in the blaze and put up a blower or close the stove door, so that the gases evolved will rush up the chimney. No. 1. Parts by weight: Copper sulphate 7, coarse salt 6, ammonium chloride 8, saltpeter 5, fine sand 2, coke dust 2. Mix well. No. 2. Chloride of sodium 7, potassium nitrate 4, cuprous sulphate 7, muriate of ammonia 8, flour of sulphur, small quantity. The "Scientific American Cyclopedia of Formulas" contains thousands of useful formulas and processes, and will be found very valuable. It is sent, carriage paid, for $5.

(12664) I. N. V. asks: What is a jet propeller and what experiments have there been made in that line? A. Jet propulsion is a method of propelling a boat by pumping in a stream of water at the bow and driving it out at the stern below the water line. The reaction of the water outside against the jet causes the boat to move forward. Many efforts have been made to produce a successful result but all have been failures, returning but a small per cent of the power expended. We have published the accounts of these experiments as they have been made in the past, and can send you eleven papers upon the subject for ten cents each. You will also find valuable material in Kent's "Engineers' Pocket Book," which we will send for $5.

(12665) J. F. McG. writes: In the issue of June 1st of the Scientific American appears a question by W. O. E. (No. 12643) about the duration of life of toads and frogs in rock. By your reply, it would seem you place no credence in the idea of these creatures having a long life, almost indefinite, under certain conditions. Permit me to supplement W. O. E.'s question by relating what I was an eye witness to, viz., a toad being taken out of rock and still alive. This district is a limestone region, the layers of rock running from an inch to eight inches in thickness, and along the river valley this rock is right at the surface, blasting being necessary from the start in any excavation work. Now a well was blasted out in this vicinity, and during the process, when at a depth of fourteen or fifteen feet, a small cavity was disclosed in which was a fair-sized toad. Mr. Toad was put on top of the bucket and hoisted to the surface, and to all appearances was dead. He was tossed out into the sun, but strange to say, his dormant condition began to disappear, and it was not many minutes before Mr. Toad was hopping around like any other one of his kind, the only difference being he did not exhibit ordinary toad intelligence, as evidenced by his lack of judgment when he hopped plumb into a batch of fresh slaking lime. He was fished out with a hoe, but whether he survived this treatment or not, I do not pretend to know; but the fact remains he came out of a rock hole at a fair depth, and the question is, how did he get into such a place, and how long had life been existing in him?

NEW BOOKS, ETC.

Forney's Catechism of the Locomotive. Third Edition. Revised and enlarged by George L. Fowler, Associate Editor *Railway Age Gazette*. New York: The Simmons-Boardman Publishing Company, 1912. Distributed by the McGraw-Hill Book Company, 239 West 39th Street, New York. 2 vols. 6 in. by 9 in. Price, $5, sold separately per vol. $3.

Books, like individuals, have their histories, and Forney's "Catechism of the Locomotive" practically originated in a translation of Kosak's "Katechismus der Einrichtung und des Betriebes der Locomotiv," which the editors of the *Railroad Gazette* had made intending to re-publish it in their journal. This translation was submitted to Mr. Forney for revision and adaptation, but he found that the scope of Kosak's work was too limited for American practice and requirements so that while retaining the "idea" of a Catechism and following the general plan of Kosak's work, he so far extended and enlarged upon it as to make it substantially a new and original book. The late Mr. M. N. Forney was one of the highest authorities in locomotive engineering, and those of us who had the privilege of knowing him will remember not only the remarkable depth of his information, but his rare ability to clothe his ideas in concise, clear and simple language, making his meaning "plain to plain people." These endowments enabled him to write a book, the object of which was "to furnish a clear and easily understood description of the principles, construction and operation of the locomotive engine of the present day, a subject which is not concisely or adequately treated in any one similar book." This work was published in 1873, and it was the best known and most widely studied book on the subject in this or any other country. It was afterward revised by Mr. Forney and a second edition was published in 1889. Since then the locomotive has undergone great changes, not only in size but in construction and operation, and a third edition of the book became necessary. This work was intrusted to Mr. George L. Fowler, an eminent engineering authority, who was a friend of Mr. Forney, and who had been asked by the latter to undertake the revision, with the result that we have in the present edition by far the most complete presentation of the subject that has appeared and one which will not only be indispensable to all who are engaged in the management, construction and working of locomotive engines, but a most useful book to a large class of readers and students in this country and in Great Britain who, while they are not connected with railways, have a deep admiration for the locomotive—the most interesting form of the steam engine. In preparing the new edition, it was found that the great increase in size and complexity of the locomotive engine necessitated the introduction of much new matter, such as the system of compounding, the introduction of the Mallet engine, the superheater, the Walschaerts valve gear, the mechanical stoker, and recent extensive improvements in the air brake system, as well as other details. It was, therefore, decided to break the book into two volumes, making each complete in itself. The first volume deals with the practical construction and operation of the locomotive in a way to make it intelligible to men who have not had the advantage of a technical training. There are 743 questions with their answers, 644 pages and 475 illustrations, to which are added six folding plates of locomotives, valve gears and air brakes. The colored diagrams showing the construction and operation of the Westinghouse air brake and of the Stephenson and Walschaerts valve gears are admirably full and clear. The second volume discusses the same points more theoretically, but always in simple language devoid as far as possible of mathematical calculations, and shows why locomotives are built as they are and the principles of their operation. This volume comprises 375 questions, with their answers, 293 pages and 190 illustrations. The letterpress and engravings are all excellent, and last but not least, each volume has a full and carefully prepared index by which the reader can readily refer to any particular topic in the book.

Unity in Nature. An Analogy Between Music and Life. By C. E. Stromeyer, M.I.C.E. London and Manchester: Sherratt & Hughes, 1911.

It would be difficult to find a book at once so metaphysical and yet so practical. An engineer by training and experience, it is to be expected that Mr. Stromeyer is not in sympathy with some of our modern scientific ideas. He does not like our current conceptions of the ether, for example, and substitutes a theory according to which space is filled with a thin gas. So, too, we find him dissatisfied with current conceptions of energy. He still adheres to the old definition of energy as a product of force into distance. Nowadays the principle of action and reaction is more strictly adhered to. Most excellent reading is to be found in the essay on "Science and Soul of Music." This is indeed a splendid piece of illuminating writing. Perhaps the most amazing characteristic of the book is its diversity of subject matter. It would hardly be expected even in a book on the unity in nature to find essays on "Flatland," "The Essence of Music and Life," "The Fourth Dimension," "Geological Records," "State Incongruities," "Urbanism," and "Ruralism." Yet the author has woven them together in a most ingenious fashion.

The Why and Wherefore of the Muffler and Cut-out

By Harold Whiting Slauson

ENGINEERS have been laboring for years to produce the silent car. Months of constant experiment have been spent in efforts to evolve a quiet transmission or forward train of gears, and only by the use of special bearings and accuracy and detail to the thousandth part of an inch have the results as exemplified in the modern automobile been obtained.

But of course the noisiest part of a car is the motor, and anyone who has attended a road or a track race will bear witness to the fact that the power plant announces its importance in no uncertain terms when its exhaust is unrestrained by a muffler. And for good reason does an unmuffled and healthy motor make itself heard, for it is a tremendous power that is harnessed in the cylinders and made to expend its energy in forcing down the pistons. Each explosion in each cylinder generates a pressure approximating 250 pounds on each square inch of piston surface. This means that, in a 50 horse-power, four-cylinder motor, a force of nearly three tons is concentrated on each piston with every ignition of the charge in that particular cylinder. Or, if we consider the gas engine as a whole, a total of over 5,000 tons is exerted on the pistons each minute that the motor runs at normal speed.

These are imposing figures, and it may be wondered why such a gasoline motor develops *only* 50 horse-power, but it must be remembered that this force is not applied continuously but that it is divided into a number of three-ton "hammer blows" of short duration. After the first "impact" the pressure decreases until, at the end of the stroke, it is scarcely sufficient to overcome the friction of the motor. But though the three-ton energy of each explosion is soon expended, there is still a considerable force, amounting to three or four times the pressure of the atmosphere, that must be disposed of at the bottom of the stroke. This is the exhaust, and when this pressure is suddenly turned loose into the open air by the quick motion of a valve, a sharp report is bound to occur, for the force in question is really the "tail end" of the explosion that has but just taken place in the cylinder. Let two thousand of these "tail ends"—each of which is pretty vigorous by itself—occur in a minute, and it will be realized why "ear-splitting" is a mild term to apply to the unmuffled exhaust.

Now to many of us, the term "muffle" may convey the idea of to choke, or cover up, and this, in a sense, is what the muffler does to the noise of the explosion. But the muffler does not throttle the exhaust with a high hand and say, "You shall not escape," but rather does it lead the gas to expend its energy by easy stages. It does this by providing a chamber in which the exhaust gas may be expanded before reaching the outside air. If the exhaust were carried through a series of expansion chambers, it would have become quite meek and subdued by the time it was discharged, for as it expands, so its energy—and consequent noise-making ability—is expended. But in order to save space and weight, many mufflers are in the form of a single expansion chamber provided with a series of "baffle plates," or disks, containing a number of perforations through which the gas passes, and thus the exhaust expends most of its energy in these and is rendered practically harmless by the time it has reached the place where it could make any impression on the human ear.

Many motorists consider the word "muffler" to be synonymous with "back-pressure," and as they know that this latter term means a resistance to the passage of the exhaust gases and a consequent reduction in the power developed by the motor, some of them have come to look upon the muffler as a power-absorbing device. In consequence of this belief, the cut-out, by which the exhaust gases are allowed to escape directly into the open air without first passing through the muffler, has become one of the most used—and abused—accessories of the car. Its *abuse* has become so flagrant, in fact, that many cities and towns have enacted ordinances prohibiting its use, and it is looked upon as the one device that is setting at naught the efforts of the designers and builders toward the production of the silent car.

It may be that the old type of muffler, provided with many obstructions to the passage of the exhaust gases, produced an appreciable amount of back-pressure that absorbed some of the power developed by the motor. The power plant of the modern car, however, is equipped with a muffler of a type that, by means of especially-shaped passages and expansion chambers, enables the speed of the out-rushing gas to be increased so that the resistance of the muffler may be nearly overcome and the amount of back pressure will be reduced to very small figures. In fact, tests that have recently been made on several motors when run both with and without the muffler in place have shown some surprising results. These tests demonstrated that, for all practical purposes, the muffler produced no diminution in the power developed by the motor at slow and medium speeds. On the contrary, some of the tests showed that the motor produced slightly more power at 700 and 800 revolutions per minute with the muffler in place than was the case when this "noise reducer" was removed. At speeds of 900 and 1,000 revolutions per minute there was but little difference noticeable; but at speeds at which the motor began to deliver its maximum power, a slight loss could be detected with the muffler in place. At 1,400 or 1,500 revolutions per minute this power loss amounted to slightly over five per cent of the total energy delivered to the dynamometer without the muffler in place.

The mufflers used in these tests showed back-pressures varying from zero to three and five pounds per square inch. Consequently it is possible that an old muffler, of poor design and clogged with soot and carbon, may absorb slightly over ten per cent of the maximum power of the motor. But the interesting feature of these experiments lies in the fact that they show the power loss caused by the muffler to occur *only* when the motor is operating at high speeds and delivering its maximum energy. But even the smallest car is capable of attaining speeds well over thirty miles an hour, and it is evident that the full power capacity of the motor should never be required in cities or towns. Consequently, it is only in the open country in which the maximum speed can be attained, or in the ascent of a steep hill in which the full power of the motor is required, that the cut-out is of any advantage in reducing the back-pressure offered to the exhaust. And even in those instances, the advantage gained by the elimination of the muffler is problematical, and is more theoretical than practical. The sound of the unmuffled exhausts at the rear of the car gives the impression of increased power, but the effect is more hypnotic than actual and it is quite possible that the car could climb that hill or attain the same speed on that straightaway as easily with the motor operating quietly as it could with the explosions making themselves evident in a stream of Gatling-gun reports trailing behind the machine.

But granting that a steep hill can be climbed faster or a higher speed on the level can be attained with the muffler cut out, what are we to think of those drivers of the high-powered cars who open the cut-out without provocation when driving through the city at a pace which could not possibly require more than a third of the power capacity of the motor? It can only be the desire to attract attention that prompts such a procedure, for the slightest movement of the throttle or spark lever will produce more power than would the most strenuous pressure on the cut-out button.

But because the cut-out has been abused is no indication that it does not possess value when properly restricted. It may be made to serve as an effective warning signal for the average pedestrian will "move" more quickly at the sound of the

short, sharp barks of the unmuffled exhaust than he will at the more musical notes of the horn. Then, too, it is the very absence of noise attendant upon the operation of the modern motor that makes it difficult to distinguish the nature of the explosions and to determine in what manner the charge is ignited in each of the cylinders. It is when it is desired to test the motor in the privacy of the garage or the country roadside that the value of the cut-out will be appreciated by the automobilist. A pressure on the button, and the explosions become distinct and any irregular firing of the cylinders can be detected instantly. Then, by turning off the ignition current from various cylinders in succession and by pursuing a process of elimination, the quality of the explosions in each can be detected and simple clues furnished for tracing any trouble to its source.

The cut-out may also be useful for preventing the occurrence of the annoying and startling muffler explosions. If the motor is turned over when the ignition current is switched off, the unexploded mixture from the cylinders will be discharged into the muffler. This will occur if the current is turned off when the motor is running at a high speed, and also when the machine is cranked preparatory to switching on the ignition current. The explosive charges that have filled the muffler will remain there until they are reached by the hot exhaust gases discharged from the motor when it runs under its own power.

These hot gases will ignite the charge in the muffler, and the violent explosions—which will at least startle bystanders, if they do not wreck the muffler—will result. If the cut-out had been opened whenever the motor was turned with the ignition current "dead," these explosive gases would have been discharged into the open air, and no muffler explosion could result when the cut-out was again closed.

The dividing line between the use and abuse of the muffler cut-out is not difficult to draw by those who have at heart the reputation of the motor car. It does seem to be difficult, however, to induce many drivers to follow that dividing line, and as "the sins of the few must be borne by the many," the present sweeping prohibitory legislation has resulted. When every driver has passed that stage in which he resembles a child with a new toy that he likes to "show off," the muffler cut-out will be a safe and valuable accessory for all motor cars. In its present status, however, the disadvantages arising from its abuse so outweigh the minor advantages that its proper use possesses, that many of even the most enthusiastic automobilists are heartily in favor of laws such as those recently passed in New York and other progressive cities.

"Heart Stopping"

(Concluded from page 73.)

To prove this, he proposes to be placed in a box, a foot of sand covering the bottom. His mouth, nostrils and ears will be filled with cotton wool and his eyes bandaged, to prevent the sand from entering his system. Then sand will be piled upon him until he is covered by at least eighteen inches of it, weighing a ton; after remaining in this position for a quarter of an hour he will be extracted alive and well. All of which reminds one of Stevenson's "Master of Ballantrae."

This athlete, interesting as he is from more than one viewpoint, got his idea of stopping his heart by reading of East Indian "fakirs." The press agent concludes with the pleasant assurance that here is another "wonder of the world."

I should like to set down certain observations regarding this phenomenon, which word I use advisedly as meaning "appearance," a term not necessarily consonant with "reality."

It is wrong to state that such muscle manipulation as that described has never before been deemed possible in medical history. Sandow, for example, in his exhibitions was able to make his muscles shimmer most amazingly in the limelight,

Many professional strong men have learned the trick.

It is possible to do remarkable things in muscle manipulation by mental concentration and exercise; the thing requires nothing more wonderful than persistency in practice during years Many of the justly praised feats seen in the circus and vaudeville are developed in this way, singleness of purpose and hard work being the only requisites Beyond this there is nothing marvelous or approaching the miraculous in them. All muscular action is dominated by the nervous system; and the nervous system has its throne in the brain; where mind most supremely manifests itself By willing it, and by constant practice, one can do wonders with his muscular system, as he can do with other parts of his body

If anyone is at a loss for an ambition in life, he may by persistent concentration and practice, so manipulate his great toe (or for that matter any other part of his body) as to increase its size out of all normal proportion Johannes Müller, in 1838, stated (and this is sound psychology to-day) that "The idea of a particular motion determines a current of nervous action toward the necessary muscles, and gives rise to the motion."

Next, as to the photograph demonstrating the decided concavity of the abdominal wall Of course the abdominal muscles are here contracted and not the stomach Protrusion of the abdomen is possible, through exercise of the mind. The literature of the *outré* in medicine contains such instances. In medical practice physicians sometimes meet women who have "phantom tumors" of the abdomen But these phantom tumors disappear when the patient is made to comprehend that she is mistaken, or should the obsession persist, these "tumors" are dissipated, and the abdomen returns to normal, under anesthesia. There are many performers who can remain under water several minutes "Odiva," it is claimed, can do this at least four minutes, which is not miraculous, but only mildly unusual. As to being buried alive for fifteen minutes, I can only repeat here that I have seen a record of the promise of such feat, but not of its fulfilment.

Statements of wonders done in the East make most entrancing romance; but they can have no standing in the court of science.

And now about that "heart-stopping." The muscles of the body are voluntary and involuntary; the former are mainly under the control of the brain and spinal cord, the latter mainly under the control of the sympathetic system But not altogether in either case For generally some cerebro-spinal filaments will find their way into sympathetic ganglia; and *vice versa*

Many voluntary movements become also involuntary; I will to take a walk; but as soon as I have got started my legs do this for me involuntarily while my mind is occupied with other things. The heart is enervated from both the cerebro-spinal system (the vagus nerve) and the sympathetic system The normal heart beat is 72 per minute, a patient fearing he has a fatal disease enters the consultation room with a pulse of 130; having been assured there is no such malady, or any occasion for such fear, his pulse beat, on leaving, has returned to normal. Drugs, again, such as muscarin and opium, will very decidedly slow the heart beat.

It seems possible then, by concentrating the will upon the heart, to quicken or slow its pulsations. But I know of no case where the function of the heart can thus be really stopped, and certainly I do not believe the idea will hold in medical science, that this can be done for twenty seconds

The alleged proof in the case before us appears to be based upon the physician having put his ear to the athlete's chest and listening for twenty seconds, watch in hand, with the result that he heard no beat. We need not question either the athlete's or the physician's good faith. But such failure to hear the heart beat does not prove there is no beating heart. The stethoscope is much more accurate than the unaided ear, and the phonendoscope still more so; the sphygmometer applied to the wrist might trace a pulse beat (which would certainly indicate a heart beat), though no beat could be elicited over the heart. I do not learn that such instruments were used. And even if, by means of the most delicate apparatus, the heart pulsation could not be appreciated, this would still not necessarily argue an absolutely non-functionating heart. Patients are moribund, comatose, for hours, with no appreciable heart beat, and yet they survive; in all that time there must have been some degree of cardiac action.

And if there were absolutely no heart beat, what would become of the blood? It cannot enter the arteries, because it has to be pumped by the heart into the arteries. It would be dammed back upon the lungs with inevitable asphyxia, and there would have to be engorged veins. But of these things no evidence whatever is vouchsafed us.

Hurrying Nature

(Concluded from page 79.)

whether success or failure has crowned his efforts. Then, possibly, he finds that one plant in a hundred has yielded something that is promising. In such crosses there is great divergence of type. It is only by selecting certain individuals in which the types desired exist and seeking to accentuate these types, that a given fruit may be built up and established. Likewise it requires many generations to get the desired characteristics fixed in a given plant Under the old system the time so consumed was such that seven years were required in establishing a new fruit. In the citrange two plant generations have been grown under the old system. The fruit that has been developed will grow anywhere in the Southern States. It takes on the nature of an improved lemon It will be more nearly a substitute for a lemon than any other of the fruits that we now have. It is still an ornamental plant and the Department of Agriculture recommends that people living in the Southern States plant the citrange in their yards as ornamental plants and derive the added advantage of being able to pick ripe fruit for citrangeade, or for any of the purposes for which lemons are used, from their own gardens at almost any time of the year. There are ten thousand people now growing the citrange trees

But had the inarch and the nurse tree been in use the citrange would have been passed through eight generations instead of two by this time. The fruit would have been much more highly developed. Many fold greater results would have been already accomplished.

But with the citrange developed as at present and the inarch discovered, there seems great opportunity in this fruit in the near future The citrange is but typical of a great number of new fruits that are just now being developed. There is the tangelo, which is a cross between the tangerine and the pomelo or grapefruit. The grapefruit is over bitter for many people and its skin is close fitting, making the meat hard to get at. The tangerine is over sweet and the kid-glove skin almost falls from it. It is easy to imagine the fruit that would result from this cross. By selection and combinations of the desired qualities by cross breeding the specimens, the scientists believe that they will be able to establish fruit that will have just the right amount of tartness and just the desired kind of skin. Already there are some specimens of the tangelo growing in Florida that are said to be in every way superior to the orange. With the use of the nurse plant and the inarch great things are expected in the next few years.

There is another application of the inarch that is just now being tested. Delicate fruits such as the lemon that refuse to grow except in a few spots in the very warmest of the United States, are being inarched upon such cold resistant plants as the mock orange. It is known that it

is the sap control of plants that protects them from frost. The lemon, for instance, keeps its leaves full of sap throughout the winter. When the weather gets sufficiently cold this sap is turned into ice and the plant is as a consequence killed. But where the lemon is inarched on the mock orange, which by nature has a sap control adapted to cold climates, the story is different. When cold weather approaches the mock orange roots refuse to send the sap into the top of the tree. It, therefore, fails to freeze and is not killed by the cold. So it is hoped that by inarching the orange, the grapefruit, the lemon, or any other of the citrus fruits upon the sturdier, related growths farther north, the danger line may be crowded into materially higher latitudes, and that even the citrus fruits of the present may be grown in a vastly wider range in the United States.

The inarch may also be extensively used in rose culture. When scientific plant growers develop a hybrid rose through this same method of cross fertilization they have been forced to wait for years until it came into flower. Some of the most delicate blossoms grow on stalks that are also delicate and slow to develop. Such seedlings may be inarched on the stalk of some sturdy and well rooted rosebush and vigorously crowded into blossom. Its virtues or lack of them may be sooner determined.

There are those who may say that practically the same things may be accomplished by the old process of budding or grafting. This is, however, not the case. Before a plant may be budded onto another stalk it must have acquired considerable age in order to produce the right sort of buds. The process of budding is most delicate and the results are in question. It is vastly slower than the inarch. It is vastly more difficult. The Government plant growers state that any intelligent man, though entirely inexperienced, can readily accomplish the inarch, while the baffling process of budding requires the most exact scientific skill.

The man who has been the moving spirit in the inarch work of the Government is George W. Oliver, who has charge of the Government hothouses at Washington. Mr. Oliver, like so many of the great gardeners and agriculturists of the nation, is a Scotchman. The greater part of his life has, however, been spent in the United States, and for many years his has been the ceaseless care that has kept the temperatures right in the Government hothouses for growing plants that range from the Arctic circle to the equator. This transfusion of the energy of one plant to another is his final success, but is merely typical of the manner in which he works the things of the vegetable kingdom and succeeds where there would seem hope for nothing short of witchery.

The "Commonwealth"-"New Hampshire" Collision

(Concluded from page 78.)

watch, all were asleep on both ships, the crews repaired quickly and quietly to their stations, and eye-witnesses on board each vessel state that there was no confusion of any kind. The "Commonwealth" backed off, proceeded to her landing, and discharged passengers and cargo. The crew of the battleship at once set about preparations for effecting the necessary temporary repairs to enable the vessel to proceed to the nearest navy yard.

These consisted of two wooden bulkheads securely bolted to the ship's sides and decks and suitably braced to withstand heavy seas from aft if necessary. By working day and night a thoroughly efficient watertight job was completed entirely by the vessel's crew in four working days. Here again theory is borne out by practice, showing that the modern battleship actually is a self-contained and independent unit, capable in an exigency of executing even such extensive repairs as were evidently necessary in this case by means of her own force of mechanics, properly directed by her own efficient officers.

Munn & Co., Inc., 361 Broadway, New York

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are *sharp*, the articles *short* and the facts *authentic* the contributions will receive special attention. Accepted articles will be paid for at regular space rates

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

Wanted—A Chief for the Bureau of Chemistry

MONTHS have now elapsed since Dr. Wiley resigned as chief of the Bureau of Chemistry. That no successor has as yet been appointed may be attributed to the fact that it is no easy task to induce a scientist of commanding position and personality to accept an annual salary far less than the sum which he could earn in a year in private practice. Moreover, the conditions under which work is now carried on in the Bureau of Chemistry would be intolerable to any really scientific man. Selfish food manufacturers are bound to do all in their power to make his official life as unbearable as possible, and the spirits that now dominate the work done by the Bureau of Chemistry in passing upon the legality or illegality of the doings of food and drug manufacturers would hardly be in sympathy with a real scientific chief. We cannot imagine that any self respecting scientist who has a reputation to sustain would be willing to accept the position without absolute power to reorganize the entire bureau, and to shape its investigations in such a way that its work will be respected. Yet, not until a thorough reorganization is effected, not until the old meaningless divisions of the Bureau of Chemistry are abolished, not until the rank and file of the Bureau of Chemistry realize that at last they may work with the impersonal, unbiased, open minds of chemists in a university laboratory of the highest standing, is it likely that the Bureau of Chemistry will become a truly effective and valuable institution. When that reorganization is effected it will no longer be necessary to maintain at an expense of tens of thousands of dollars per year a referee board to check up the work of the Bureau of Chemistry. As matters now stand, the Bureau of Chemistry has the lamentable distinction of being the only department of the Government that cannot stand on its own scientific feet, and that requires scientific supervision by another body.

At present wealthy dishonest food manufacturers find it no difficult task to escape the punishment which they so richly deserve. Opposed by well meaning but incompetent employees of the Bureau of Chemistry they find it no difficult matter in Court to offset their unscientific evidence by expert testimony, which can be bought at a market price, and which is at least as good as the evidence offered by the Government. That is why the admirable Pure Food and Drugs Act is not at present as effective as it should be. Not until a strong man is appointed, a man who realizes the enormous responsibility of caring for a nation's health, will that excellent piece of legislation become what it should be.

Scientific men naturally shrink from the kind of publicity which the reorganization and administration of the Bureau of Chemistry will bring with it. For that reason it may be necessary to appoint some fearless, honest, public-spirited civilian, who is in full sympathy with the ideals and methods of scientific men.

Interference and Aeroplane Disasters

THREE very recent accidents to aircraft have furnished food for serious reflection, and they are all the more important because we appear to be on the eve of a wide adoption of aeroplanes of one or another form for military and naval uses. In addition to this, these mishaps are likewise lessons to the aviator generally. In brief, we are brought face to face with the fact that speeding aeroplanes are a danger to one another even though maneuvering at apparently safe distances.

On the 20th of June, Mlle. Helene Dutrieu, while driving a monoplane at Aix-les-Bains, hit an "air hole," as the descending air current has been nicknamed, and fell to the ground. Her fall, however, was checked by her machine landing on top of two other monoplanes ascending at the time, and all three of the aeroplanes were thrown to the earth.

Sixteen days later, at Villacoublay, near Paris, Lieutenants Briez and Burlez, both of the French army, set out on a flight toward Belfort, a point on the eastern frontier. Lieutenant Briez got the start of his fellow aviator, and had reached a height of five or six hundred feet before Lieutenant Burlez overtook him. Lieutenant Burlez was traveling a hundred feet higher up and faster than his brother officer. Just after the upper monoplane swept ahead, a descending column of air—undoubtedly the reaction due to the overhauling and higher monoplane—struck one of the wings of Lieut. Briez's machine and destroyed its equilibrium so suddenly and forcibly that the latter aviator and his aeroplane were dashed to the earth. Lieut. Burlez was thus the innocent cause of the disaster which nearly cost his companion-in-arms his life.

It is quite probable that Mlle. Dutrieu's fall may have been brought about by the aerial perturbations set up below her by the maneuvering of the two lower monoplanes—in this respect the promoting agitation coming from beneath instead of from above as in the case of Lieut. Briez's serious plunge. We do not know what were the speeds of the two disturbing aeroplanes at Aix-les-Bains, but it is not hard to see how doubling the cause of the aerial commotion would naturally promote greater reactions, and the gravity of this under any circumstances might be augmented if the same factor of agitation occurred nearer the ground. This is broadly on the principle that a bodily displacement of the air, as that occasioning sound, for instance, will carry its effect higher than a similarly disturbing force exerted at greater altitude and transmitted downward. In the case of the Burlez-Briez accident, we are left to speculate as to what might have occurred if the lower rather than the upper monoplane had overhauled and passed onward at greater speed.

Only a few days ago, the Italian aviator, Guidoni, while maneuvering his hydro-aeroplane aloft in the Gulf of Spezia, drove his machine across the wake of the battleship "Dante Alighieri," which was at that time making about twenty-three knots an hour. The high speed of that battleship created such perturbations in the air that Guidoni's machine, although some distance astern, was capsized and tumbled into the water. This is especially suggestive to the naval man, because the use of the hydro-aeroplane is proposed in conjunction with sea-going ships as mobile launching and landing places for these hybrid scouts. The tumble which Signor Guidoni got under auspicious conditions of wind and water does not prophesy favorably for the employment of aeroplanes with moving vessels and in more boisterous circumstances of wave and weather.

But what all three of these illuminating mishaps emphasize is the wide zone of disturbance set up by the reactions of the air following a moving body. Model basin experiments and the influence of ships in motion have given us convincing evidence of the force of the suction created between neighboring vessels under way. Because of the denser character of the medium supporting floating ships, it is reasonable to suppose that the action of readjustment of the surrounding water is confined to a relatively restricted zone when compared with similar disturbances created in the air. And yet we know that moving craft have affected one another by suction when separated several hundred feet. Because of the compressibility and the far lesser density of the air, it must be plain that a flying machine—not a balloon—is drawing for support upon a much wider atmospheric zone than a similar weight borne upon the water's surface. Again, the compressibility of the air is a prime factor in sustaining a heavy body in motion aloft, and the re-expansion of this air in the wake of the aeroplane must produce perturbations which carry their influence correspondingly farther because of the very nature of this medium. Therefore, at first blush, it seems that the flying machine in flight must be given a wider berth by another aeroplane than heretofore imagined. The question is, what will this impose when air craft of this sort undertake to operate in squadrons? Formations of this kind may logically follow the adoption of the aeroplane gun.

It has been intimated by some students of this problem that the propellers of the aeroplanes were principally responsible for these disturbances leading to the formation of falling columns of air, otherwise popularly known as "air holes" or "air pockets." That there is good reason to doubt the entirety of this perturbation being due to the propellers has been disclosed by the towing tests of models in the experimental basin. The researches of this character have shown pronounced suction to e[illegible] vessels without screws, and Na[illegible] has declared his belief that [illegible] momentous factor in promoting [illegible] that a somewhat kindred co[illegible] between the propeller of a fl[illegible] porting planes which are be[illegible] bluntly against the opposing a[illegible] it is contiguous to these sur[illegible] jected to its greatest comp[illegible] the points of suspension, a[illegible] the wake of these planes [illegible] of the vertical agitation [illegible] recent accidents suggest a [illegible] gation which might be p[illegible] art of aerial navigation, [illegible] these casualties can not ri[illegible]

The Protection of M[illegible] from L[illegible]

NOWHERE else do [illegible] the atmosphere assu[illegible] fying a character a[illegible] mountains, and the danger [illegible] of the formidable obstacles [illegible] tion of mountain observato[illegible] of the *Comptes Rendus*, M. J[illegible] founder of the Mont Blanc o[illegible] graphic description of these [illegible] and some suggestions for averti[illegible]

It is a mistake to suppose that t[illegible] by snow suffices to protect from [illegible] was illustrated last August, when [illegible] the Society of Observatories, bui[illegible] of Mont Blanc, was struck by li[illegible] results to one of its occupants. T[illegible] wood, roofed with sheets of copper, [illegible] vided with lightning rods. It was p[illegible] in snow at the time of the disaster. T[illegible] was struck in 1909, although it did [illegible] metal roof.

The famous Janssen observatory on [illegible] was repeatedly struck, although it bo[illegible] lightning rods, connected by cables to [illegible] few hundred feet distant. This building [illegible] and was built on the snow. The effects of [illegible] were extraordinary and appalling; the m[illegible] ware was frequently melted or perforated; [illegible] and nuts in the walls were melted; the wood[illegible] charred; the metal cap of the large telescope [illegible] pierced with holes, etc.

In 1903 a guide, one Felix Boson, witnessed a [illegible] liant electrical discharge in the form of ribbons [illegible] fire which for two hours and a half continued to [illegible] across the interior of the building, proceeding [illegible] one of the cables connected with the lightning [illegible] In 1902 a ball of fire as large as a pigeon's egg [illegible] seen to move slowly across the room, then retreat[illegible] a distance and explode, giving a violent shock to [illegible] persons present. In 1907 a series of lightning st[illegible] occurred one evening at nearly regular intervals [illegible] a few minutes; each stroke produced a deafe[illegible] noise and was attended by sparks like fiery serpe[illegible] which shot through the observatory in all directi[illegible] This process continued nearly an hour. Such o[illegible] rences appear to have been common at the Ja[illegible] observatory, which must have been a far from tran[illegible] place of abode for the savants who carried on his[illegible] researches at this elevated spot.

It is evident that lightning rods are entirely ina[illegible] quate to carry off the enormous discharges of mount[illegible] thunder storms.

In contrast to the experiences of the former Jan[illegible] observatory, it is most encouraging to learn [illegible] M. Vallot's own observatory, on another part of [illegible] Blanc, has never once been struck by lightning, du[illegible] its thirteen years of existence. This structure is b[illegible] on the solid rock, and is completely incased in [illegible] sheets of copper, which are connected with a n[illegible] of multiple-point lightning rods, grounded in the [illegible] The whole system of metal thus forms a Far[illegible] cage, which so fully carries off the lightning disch[illegible] that even during the most violent thunder st[illegible] no electrical effect of any kind is observed inside [illegible] building, despite the presence of numerous met[illegible] instruments which are not connected with the light[illegible] rods. M. Vallot's observatory therefore forms a v[illegible] ble object lesson to anyone who is contemplating [illegible] erection of a mountain observatory.

Danger in Metal Wine Vessels.—A note of warning [illegible] regard to the use of metal utensils for the measuri[illegible] serving, or holding of wine is sounded in the *Mon[illegible] Vinicole* by M. L. Mathieu. In general only co[illegible] plated copper, or silver should be permitted in [illegible] rooms, cellars, etc., though plated "tin" may be [illegible] safely under certain special conditions. Zinc is espe[illegible] prohibited, since it forms with wine salts which are [illegible] ble in the wine, and which not only impair the flav[illegible] lending a disagreeable metallic flavor, but are [illegible] toxic even in very small quantities.

Science

The Temperature of Flowing Lava was measured during the eruption of Etna last September by Prof. G. [illegible] with a Fery radio-pyrometer. Where the lava was still glowing red, temperatures ranging from 795 to [illegible] deg. Cent. were observed.

[illegible] Sizes for Scientific Books.—The council of the International Association of Chemical Societies, [illegible] in Berlin last April, unanimously approved Prof. [illegible] suggestion in favor of a uniform size, or series [illegible] for chemical publications, and recommended [illegible] affiliated societies adopt the universal format [illegible] centimeters, or a format bearing some logical [illegible] this. All publications of the Association will [illegible] conform to this size.

[illegible] of Rain Making.—Prof. Willis L. Moore, [illegible] Weather Bureau, has issued a statement in [illegible] the efforts of a prominent breakfast [illegible] of Battle Creek to produce rain artificially. "[illegible] hardly seems necessary for the Weather Bureau at this late day," says Prof. Moore, "to enter into elaborate arguments in order to convince the public of the utter futility of this and every other method so far proposed for artificially producing rain."

Natural and Artificial Asphalt.—In several European countries, and especially in Austria, artificial asphalt is manufactured and used; but up to the present there has been no direct comparison of the two from the purely chemical standpoint. Recently, however, Gawalowski has made analysis of true Barbados asphalt and of the artificial, with the following results: Specific gravity, natural, 1.0143; artificial, 1.393. Hardness according to Mohs, natural, 1 to 2 deg. M.; artificial, 2 to 3 deg. M. Hardness according to Breithaupt, natural, 1 to 2 deg. B.; artificial, 3 deg. B. Soluble in petroleum, natural, very easily; artificial, with great difficulty, slowly and incompletely. Soluble in benzin, natural, very easily and completely; artificial, with great difficulty, slowly and incompletely. Soluble in benzol, natural, very easily and completely; artificial, rather easily. Solubility in wax, natural, not known; artificial, in 5 to 7 days, leaving an amber-like remainder. The solution in benzin of the Barbados natural asphalt gives a beautiful brownish varnish layer, which dries in about ten minutes; that of the artificial asphalt, however, does not; therefore the first is to be preferred for fine varnish.

The Bulk and Weight of Our Rainfall.—Mr. George A. Lindsay, writing in the Transactions of the Academy of Science of St. Louis, gives some interesting statistics of the rainfall of the United States, not expressed in the conventional inches of depth, but in the aggregate volume and weight of the moisture that falls annually over a given area. To anyone who is familiar only with the customary method of stating rainfall, it is somewhat startling to learn, for instance, that 43.9 cubic miles of rain fell in Missouri during the year 1896. This is decidedly more impressive that the statement that the rainfall was about 40 inches. In the same year 1,296.4 cubic miles of water is computed to have fallen over the whole area of the United States, and the average annual rainfall is somewhat greater than this; viz., 1,308 cubic miles, weighing 6,000,000,000,000 tons. As an illustration of the fact that most of the water that falls as rain never reaches the sea through the medium of drainage, but is evaporated from the land, Mr. Lindsay shows that the discharge of the Mississippi River at St. Louis is but little greater than the volume of rainfall over the State of Missouri alone, despite the enormous area drained by the river above that point.

Street Dust and Street Pavements.—In a recent article published in *Hygiene* Dr. Rasser draws attention to the considerable danger connected with street dust, the action of which on the human organs of respiration is responsible to a great extent for the origin of tuberculosis and similar diseases of the lungs and wind-pipe. But apart from this kind of trouble, dangerous chronic inflammations of the eye should be put down to the action of street dust. In fact, an increase in the frequency of catarrhs has been observed with continued dry weather and a reduction on the occurrence of the first rain. Under these conditions road engineering, apart from its technical task, has primarily to fulfill a sanitary task. As the production of dust depends on the fixing of roads, a pavement complying with all hygienical requirements should be looked for. Asphalted streets would seem to comply with most of these conditions, provided there be an extensive and thorough removal of waste matter followed by an abundant sprinkling of the road surface. Caoutchouc pavement, as used with especially satisfactory results in London, would seem to be most desirable. Dr. Rasser does not seem to think very highly of the sprinkling of roads with chemicals, such as salts and tar. An ideal means of laying street dust which has been suggested of late years is sprinkling with a solution of sulphite pitch in water, which would seem to avoid any dust for at least six weeks. Sulphite pitch is obtained as a by-product in manufacturing cellulose.

Electricity

Electrical Irrigation.—At Good Ground, L. I., Mr. Emilio Olsson is conducting some experiments with his system of irrigation, described some time ago in the Inventor's Department of the SCIENTIFIC AMERICAN. The poorest soil in Good Ground has been selected for the test. One plot is irrigated with water alone; a companion plot with water electrically charged, according to the Olsson system. The results of the comparative growth will be watched with interest.

An Electrically Fired Iron Furnace.—The electrical production of pig iron has been tried from time to time in Scandinavia, the poor coal supply of the country and the availability of cheap electric power inviting such experiments. In a powerful reducing plant erected at Trollhätten, investigations lasting six months have recently been concluded. The energy was supplied at 10,000 volts, three-phase, and transformed to two-phase current with a pressure variable in each phase from 50 to 100 volts, and currents of 3,000 to 18,000 amperes were employed in the furnace. The best result attained was 2,241 kilowatt-hours per ton of iron cast, of which 1,596 kilowatt-hours was expended in useful work, showing an efficiency of 71.77 per cent. The furnace is designed to produce 7,500 tons of pig iron during eleven months of the year.

Communication with Railroad Trains by "Railophone."—A demonstration of the "Railophone," an invention for actuating signals and effecting other mechanical operations on moving trains, was recently given on an English railway. Briefly the system comprises an insulated wire laid alongside the track and connecting to apparatus at signal cabins and stations, and of a pair of coils wound on frames around the railroad cars, one for sending and the other for receiving. The system operates by induction, and an essential feature is a relay which can only be operated by the periodic impulses which convey the signals and is not affected by the nonperiodic vibrations caused by the movement of the train. Among other feats accomplished during the tests were the stopping of a train which had been allowed to run past a danger signal and the transmission of a message and its reply between a station and the train.

The Hamburg Electric Railroad.—The new Hamburg elevated and underground electric road is a remarkable piece of engineering and electrical work and represents the most recent progress on the continent. It is made up of viaducts and bridge structure for about one third the length, and a quarter of the length is underground. The remainder is built of embankments, in part, between masonry walls. Trains are made up entirely of motor cars, each one having two 100 horsepower motors, and the controlling can be done from each of the end cars. The total length of the line is about 16 miles, with standard gage tracks, and the distance between stations is 2,650 feet. The station platforms are 200 feet long. An automatic system of electric lighting is used so that the lights come on only when passing through the underground part. Three-phase current at 6,000 volts is supplied by a special plant at Barmbeck, sent to two sub-stations at the principal station of Eppendorf, where it is transformed to 800-volt direct-current. This is employed on the third-rail system, but the contact shoe works upon the under surface of the rail.

A Marvelous Electrical Discovery.—In a brief and revolutionary monograph presented to the French Académie des Sciences, Prof. Jean Becquerel, the great physicist, announces a discovery which, when it is confirmed, as it certainly will be, will prove to be of untold importance in the practical workings as well as the study of electricity. It is well known that if a thin strip of metal is fastened to a glass plate placed between the poles of an electro-magnet in such a way that the plane of the strip is at right angles to the lines of force of the magnetic field, a current passing through the strip from end to end is deflected to one side or the other, according to the type of metal of which the strip is composed. Thus the current in a strip of zinc, iron, or cobalt is deflected toward the right, but to the left if nickel, gold, or bismuth is used. The effect is especially striking when bismuth is taken to make the strip. From its discoverer, Dr. Hall, of Johns Hopkins University, this has been named the "Hall effect." It has been held as strong evidence that there are such bodies as positive electrons. Dr. Pfund of Baltimore is, together with Sir J. J. Thomson and others, convinced that the presumptive evidence in favor of the existence of positive electrons is too definite for further doubt. M. Becquerel now proves that if the Baltimore experiment be carried out with a piece of bismuth in liquid air, the effect is made more conspicuous. Then, too, if the magnetic field be increased to above 3,500, the deflection abruptly becomes positive instead of negative. This upsets all known mathematical and physical theories that would make the negative electrons the only carriers of electrons in metals. It again changes our views of the question of what negative and positive electricity really is.

Aeronautics

A New French Aero Club.—Blériot, who resigned on July 3rd last from the Aero Club of France, has started a new organization, called the Aviators' Friendly Association. Among his adherents are many famous aviators and designers.

France and the Gordon-Bennett Cup.—There has been much activity at Chalons. The elimination trials for the Gordon-Bennett cup have shown that Vedrines will, in all likelihood, represent France. Recently he covered 200 kilometers (about 120 miles) in one hour and twenty-four minutes.

A Berliner Engine.—Mr. Emil Berliner of Washington, D. C., well known in connection with his telephone and other important inventions, has patented a rotary gas engine which has a rotating crank case carrying a cylinder which rotates with it, and a piston in the cylinder with the ports of the cylinder so disposed as to be uncovered by the piston as it reaches the end of its stroke following explosion.

A New Aeroplane Construction.—Spencer M. Brown of Portland, Ore., has patented an aeroplane, No. 1,032,-587, which has a pair of upwardly inclined wings which are united at their lower edges and each of the wings is broken into transversely disposed sections, with each alternating section along the inner edge of each wing inclined upwardly to form with the other section a truss-like framework.

A Sixteen-hour Journey in a Dirigible.—The French dirigible "Conte" has made a trip lasting sixteen hours and twenty-four minutes. Under the direction of M. Cohen the craft left from the vicinity of Meaux and Fontainebleau, returned over Paris in the dead of night, then reached Etampes, Arthenay, and Chartres, finally to return to Issy-les-Moulineaux. The maximum altitude attained was over 6,500 feet.

Resistance Tests With Blériot Machines.—The French military authorities have been making some remarkable tests with Blériot monoplanes. On a special railway train a Blériot monoplane was mounted in such a manner that it could assume all possible positions taken in ordinary flight. The train was driven at a speed of 72 miles an hour over a 5-kilometer stretch of railway.

Investigating Accidents.—The Public Safety and Accidents Investigation Committee of the Royal Aero Club promises to fulfill a useful purpose in the development of aviation. Judging from the celerity with which it proceeded in investigating the accident that occurred recently at Brooklands, in which an aviator and a passenger lost their lives, we may expect to learn more of those weaknesses in construction and defects in handling to which so many deaths are due.

German Military Aeronautics.—The German Minister of War has bought for the army the Siemens-Schuckert dirigible airship. In trials conducted last February the vessel attained a speed of 43 miles an hour. The dirigible "Z-2," stationed at Cologne, a Parseval airship, and fifteen or twenty aeroplanes will take part in the forthcoming maneuvers. The dirigible "Z-3," which was badly damaged at Friedrichshafen, is now completely repaired.

The Blériot Berline.—The aerial taxicab or berline, built for Deutsche de la Meurthe by Blériot, has been making some remarkable flights. The 100 horse-power motor has been removed, and in its place a 140 horse-power engine has been installed. Loaded with about 650 pounds of ballast, it carries a cargo equivalent in weight to that of four passengers besides the pilot. As yet, no four passengers have ventured to take their seats in the taxicab body.

The First Aerial Derby.—The English Aerial Derby showed that flying can be made a real sport. More enthusiasm was invoked over a contest for a 100 guinea trophy and cash prizes of £450 than was aroused even by the $50,000 prizes of the *Daily Mail* in the past. It is safe to say that millions saw the race. At the London Aerodrome, we are assured by our contemporary *Flight*, at least 45,000 paid for admission to the inclosures, while on the adjacent slopes several thousands more were massed. The same state of affairs applied at every point around the course of 81 miles. Hamel, one of the contestants, stated that Esher Common was absolutely black with people.

Guiding Torpedoes from Aircraft.—In patent No. 1,032,394 Bradley A. Fiske, U. S. navy, presents a method and apparatus for delivering submarine torpedoes from aircraft in which the torpedo is first transported through the air to a point of desired proximity to a target by means of an aircraft and then the torpedo is trained in the desired direction, after which the propelling mechanism of the torpedo is started, and then the torpedo is released to fall by gravity to the water. In the apparatus, a strap is employed for retaining the torpedo below the aircraft and a manually controlled lever releases a latch for said strap, the said lever also actuating transmitting mechanism to operate the starting device for the propelling mechanism of the torpedo.

On striking the timber the motorcycle acquires a mounting position.

Position of the machine two feet above the testing track on a ten foot leap.

Machine's position in alighting after striking the timber obstruction.

Testing a Motorcycle

A MANUFACTURER of motorcycles in the Middle West experienced considerable difficulty in his early days with spring forks. He was using a very high grade of steel, but nevertheless the forks would sometimes break in the hands of bicycle users. They employed consulting engineers to find out what was the matter. The verdict was that the spring forks were the best that could possibly be made. One engineer, however, had made a change—not a change in design, but a change in material—substituting a steel somewhat more brittle. That seemed very foolish. In order to prove to the manufacturer that he was right, he offered to test the motorcycle in the manner shown by the accompanying illustrations. He rode around a test track, banked at the turns, at a speed of five to sixty miles an hour, striking an obstruction (a four by four timber). Every time the motorcycle encountered the obstruction it leaped into the air approximately two feet and alighted ten feet farther on. The test is now being performed by several testers daily.

Transatlantic Wireless Telegraphy Without Antennæ

HUGE towers for carrying up the antenna system to sufficient height above ground have been built at several places, e. g., Poldhu, Clifden, Glace Bay, to make transatlantic radio-telegraphy possible. The highest building in the world, the Eiffel Tower (about 1,000 feet in height), has in its turn been utilized for the purposes of wireless telegraphy, while the sending tower of the Nauen radio-telegraphic station was recently raised from 330 feet to 660 feet in height, thus allowing the African colonies to be reached from Berlin by wireless telegraphy.

It will therefore be readily understood that experiments recently made in Berlin with a new arrangement due to Prof. Zehnder should arouse more than usual attention. The new scheme, in fact, does away with any antenna. An ordinary insulated conductor wire carried on telegraph poles is connected at both ends to the ground, with or without the intermediary of Leyden jars. The total length of wire between the two ground connections should at most equal one half wave length of the alternate current employed. If, for instance, the wave length in air be 4,500 meters (2.8 miles), which is about sufficient for transatlantic operation, the ground connections would have to be located at 900 meters (2,952 feet) apart in the ground and only 250 meters (820 feet) in water. This conductor is excited as usual in its central part by a Braun vibratory circuit, the length of which is tuned to the frequency of the vibratory circuit.

The new scheme at the same time constitutes a system of directed wireless telegraphy, the direction of the wire itself being the most favorable for sending. In a like manner, if a receiver be substituted for the exciter, the preferential receiving direction will be given by the wire.

This scheme, in spite of the provisional character of the arrangement, allowed telegrams to be sent with small-size sending apparatus and without antennæ, to many hundreds of miles. Herr Kiebitz, of the German Telegraph Department, in his experiments on behalf of the department transmitted radiograms from Berlin to Norddeich and with the ordinary type of receiver, received in Berlin messages that came across the Atlantic Ocean from Glace Bay, Nova Scotia.

One advantage of the scheme suggested by Zehnder is the possibility of installing the whole of the apparatus in the interior of a building, fortress, man-of-war, etc., thus protecting it against destruction by storms, gales or the enemy's guns, which will be found of inappreciable value in warfare. Incidentally these experiments appear to show that the transmission of electric waves in great part occurs through the earth itself.

The Curtiss "Flying Boat"

A New Type of Hydro-aeroplane

SINCE he closed his camp and aviation school at San Diego last spring, Glenn Curtiss has been steadily at work at his home in Hammondsport, N. Y., making further improvements upon his hydro-aeroplane. The result of his recent experiments is shown in the photographs reproduced on this page, which give a good idea of his latest combined boat and biplane, known as the Curtiss "Flying Boat."

This boat is a single step hydroplane, 26 feet long, 3 feet wide, and having sides 3 feet high. It is surmounted by a regular Curtiss biplane, having planes of 30-foot spread by 5½-foot depth between the planes. The planes contain a total supporting surface of about 320 square feet, and support, when in flight, a total weight of about 1,000 pounds. As many as four people can be carried comfortably. One of our illustrations shows a man in a bathing suit lying on the deck of the boat behind the planes in addition to the pilot and passenger in front.

The power plant consists of an 80 horse-power Curtiss 8-cylinder, V-type engine and single propeller mounted high up between the main planes at the center. The motor is mounted sufficiently high to provide a liberal clearance between the end of the propeller blades and the boat, the propeller being just back of the main planes, as usual.

Above the tapered hull of the boat, at the rear, is a vertical fin terminating in a large vertical rudder. The tail is placed about half way between the boat and the top of this fin, and extends out on each side of it. The horizontal rudder consists of two hinged flaps at the rear of the two halves of the tail. No front elevator is provided, so that the pilot has a clear view in front over the spray hood that is fitted. The balancing planes are at the rear, half way between the main planes. Inclined cylindrical floats are fitted below the ends of the lower plane in case the machine tips in making a quick turn on the water.

This new flying boat of Curtiss's makes aviation perfectly safe, as one can travel 50 miles an hour on the surface of the water, or 60 or more miles an hour a few feet above the surface. It will open up to the motor boat enthusiast heretofore unnavigable streams. In fact all the unused canals and shallow rivers of the country can be skimmed over always with complete safety by the yachtsman-aviator.

The passenger lies well to the rear.

The new Curtiss hydroaeroplane in flight.

The Current Supplement

IN the current issue, No. 1900, of the SUPPLEMENT, Dr. Gradenwitz gives an illustrated account of the manufacture and testing at high tension of porcelain electric insulators.—W. R. Ingalls, the well-known metallurgist, writes on the electric smelting of zinc.—Our Berlin correspondent gives a description of the new railway station in course of construction at Leipzig, which, when completed, will be the largest in Europe.—Dr. Zahm concludes his excellent article on aeromechanics.—An instrument by means of which the blind are enabled to perceive light through their sense of hearing was recently exhibited by M. Fournier d'Albe, of Birmingham, England, at the Optical Convention. An account of this is given in the current issue.—Some very excellent points are made with regard to the Oldfield bill in comment reproduced from *Metallurgical and Chemical Engineering* for July.—A new method of preserving eggs, which is said to possess altogether superior merits, is described by our Paris correspondent.—The closing article deals with experiments on the durability of tool steel.

A New Andean Railway

THE American minister at La Paz, Bolivia, reports that on May 15th the railway recently built from Potosi to Rio Mulato, a station between Oruro and Uyuni on the main line, between La Paz and Antofagasta, was officially opened at Potosi by the president of the republic and his cabinet. This railway, surveyed, planned and built by American engineers and contractors, is regarded as a marvelous piece of construction. At one point the altitude is about 16,000 feet, making it, the minister states, the highest railway in the world. Not only was the road very costly to build, but it will be costly to maintain, apparently out of all proportion to its prospective business. There is not a village or hamlet between the terminal points; and Potosi, which had once a population of 200,000, has now fallen to 25,000.

Rebuilding Messina

AFTER the great earthquake of December 28th, 1908, which completely destroyed the city of Messina, the few survivors, aided by international philanthropy, erected temporary wooden buildings south of the old city, and here commercial and official business has since been carried on. On the original site of Messina not a single building had been erected or even begun up to the end of last year. Now, however, preparations for rebuilding the city are well under way. Since July, 1911, the systematic removal of the débris from the streets has been in progress. The plan of reconstruction includes a raise in the level and an extension of the harbor front.

From Clay to Bronze

The Craftsman's Part in the Art of Sculpture

By C. H. Claudy

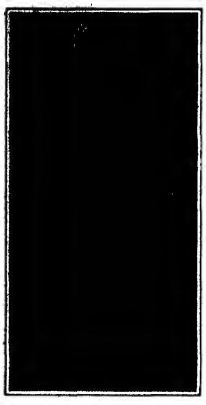
"THE clay is the life, the plaster death, and marble the resurrection." A famous artist's words, descriptive of the forms through which a statue must pass whether it end in the white marble which is so poetically referred to above, or in the sterner and more enduring bronze of the heroic size statues, too big for marble work.

Everyone knows, of course, that a statue is first modeled in clay by the sculptor, whose deft tools and skilly work out the likeness, the life—sometimes the soul—of the subject. Then, in some way, usually passed over by the expression "casting," the clay is reproduced in bronze. Of the intermediate steps, the general public knows little, yet those intermediate steps are of the utmost importance and of great interest. It is in them, as well as in the casting of the molten metal, that the craftsman steps in and replaces the artist—the place where the most highly skilled labor is necessary, and where the greatest artistic skill in statue making has no value.

When the wet clay, preserved from day to day by being constantly shrouded in wet cloth, is finished and has the life-like form of the subject to the utmost of the artist's expertness, the craftsman prepares to make a mold from the clay. This mold is not used to make the bronze cast, but it is intended to be employed for making a plaster cast of the clay. From this plaster cast, the final mold is made in which the bronze, streaming and hot, is poured. The great interest in this operation of making the plaster mold and plaster cast comes from the fact that there is no retracing the steps once made—no second chance if the first one fails. To make the mold, the clay is first stuck full of thin pieces of tin! This apparently disastrous proceeding is necessary, for the mold, when made, must be in two or more pieces and some division between the two is necessary. So many thin pieces of tin are used, and are ruthlessly stuck into the clay, forming raised partitions along what are to be the division lines of the mold. The strips overlap and project six inches from the clay. The clay is then wet down and then covered with a thin, cream-like plaster of Paris mixture, which has been highly colored with some pigment; it makes little difference what color it is, so that it is easily distinguished from white. The reason for this first colored layer is seen later on. The liquid plaster is sprinkled and thrown on the clay statue, the greatest care being taken to cover every part of it completely, and to have the liquid penetrate into all the folds, crevices and indentations of the clay. On the skill and care with which this is done depends the success of the mold.

As soon as this first colored layer has been finished, and set, it is built up to a thickness of perhaps an inch with thicker plaster of Paris, uncolored this time. Next, a framework of pipes, wood, wire and rods is erected about the statue in such a way that each part of the mold, as indicated by the division lines of projecting tin, has its own set of braces. Once these are in place, the making of the mold proceeds rapidly, with an assistant mixing plaster of Paris in a bowl, and the craftsman-caster throwing and kneading the wet masses onto the plaster covering the clay, being particular that the mold is built up the thickest where the most strains will come, where it may be five inches or more thick, and permitting those portions where little strain may come to remain not more than an inch or two thick. The iron rods and pipe frameworks are well embedded in the plaster so that they, themselves, will take most of the strain when it becomes time to lift or move parts of the mold.

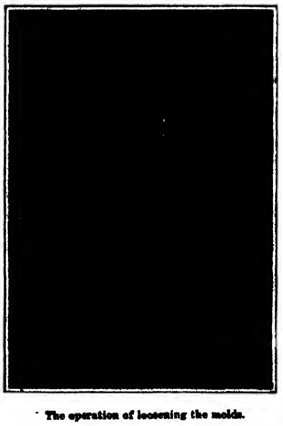
When the caster is through this part of the work, the whole is allowed to dry or set for at least twenty-four hours, and frequently longer. Next is the important and delicate operation of removing the molds from the clay. The delicacy of the process comes in because the molds do not always "pull," that is, to get the molds off, it is necessary to break the clay and to destroy it; in one of the pictures the caster (who, in this case, is also the sculptor) is removing the back pieces of the lower mold of the heroic size statue. The coat tails have been broken off in the mold, and the clay composing them must be dug out by hand, and with streams of water. The picture also shows the destruction wrought in the arms of the statue, the molds of which ruined the clay in being taken off.



The finished plaster cast.

Fitting key joints together.

Plastering the molds.



The operation of loosening the molds.

The operation of taking off the molds.

When the various pieces of the plaster mold are all removed, they are cleaned thoroughly of all clay, washed out and finally anointed with a specially prepared grease which will prevent the plaster which forms the cast to be made, from sticking. They are then assembled in place, ready for casting. In so large a statue as forms the subject of these photographs, no attempt is made to cast the whole in one piece; the legs and half the trunk form one piece, the head and chest another, the two arms are cast separately and so on. In order that the several parts should fit one another accurately, the molds are fitted together as the casts are made, and "key joints" are constructed, the raised or "dowel" part of the key being formed on the first cast made while it is still in the mold (and is covered with grease) so that the second cast when made shall form its recess or female part of the joint, thus insuring an accurate fit. The pouring of the plaster for the final cast is also a delicate operation. The plaster must not be too thin, or it will run away from some parts of the mold and settle in other portions; it must not be too thick, or it will not run into all parts of the mold. The casting must proceed uninterruptedly for each set of molds, or it may not come out a homogeneous mass. Generally, the molds, bound together with rope and wire, are turned about as the plaster is run in, to be sure of getting an even and complete casting. The molds are not filled with plaster, as that would not only make the cast very heavy, but give it an excellent chance to split from strains incident to hardening. The walls of the plaster cast, like those of the mold, are from four to six inches or more thick, but a hollow space is always left in the trunk and legs and arms of such a statue, so that in drying there is plenty of room left for air

to penetrate and get to both sides of the cast. When the molds are all cast, and the whole has dried a sufficient time, comes the most delicate part of all—getting the molds off the cast. For these will not pull from the plaster cast any more than they did from the clay. In this case, however, it is not the cast but the molds which are broken in removing them, and now the significance of the colored layer in the mold becomes apparent. The caster, working away at his molds with mallet and chisel, is safe so long as only white chips fly, as soon as he gets to the colored layer, he goes most carefully, knowing that immediately beneath it lies the cast. The molds are taken off in many pieces and thrown away; their function finished, what remains is a plaster cast, exactly like the original clay, which may be shipped away to the bronze factory (as the clay could not be shipped) there to have molds made in many pieces into which the bronze is poured.

Large statues like the one illustrated take several days to cast both mold and plaster cast, and at almost any time, the labor of months of sculpturing may be ruined by careless work. Of course, molds are broken in making and statues in plaster are chipped. These accidents are not necessarily ruinous, as besides in either mold or finished cast can be repaired. But the destruction of the clay that the plaster mold may be made, the destruction of the mold that the plaster cast may emerge, like a butterfly from the cocoon, is a delicate operation, and one mistake in the caster's art or one slip of the chisel may mean, if not destruction, at least grave danger to the success of the whole. Hence it is that the craftsmanship of the caster takes for a while the place of the artist, and becomes as much a necessity to the production of the finished likeness as all the skill within his fingers.

A New Form of Underwater Attack

A Torpedo that Carries a Gun

By Robert G. Skerrett

WITH the exception of some ships now building or planned, the thousands of tons of armor plate carried upon modern fighting craft are designed exclusively to combat passively the attack of various types of gun-fired projectiles. Below the load-line, these vessels depend for security upon the surrounding water, so far as the attack of artillery is concerned. The torpedo has commonly in the past been considered so limited in its range and so uncertain in its performance that but little weight has been attached to it by the partisans of the gun. Battle ranges seemed logically to keep the torpedo in the background, except at night, when the speedy torpedo-boat counted upon getting near enough to launch its weapons with a more reasonable promise of getting home a hit. The naval constructor, accepting the torpedo at its potential value as seen by the majority of the fighting officers, simply limited his efforts to frabricating the under-body of his fighting craft so that the damaging effects of a chance blow from a torpedo should be confined to a restricted area. Hence the inner and the outer bottoms, and the water-tight, cellular divisioning of the intervening space. As a matter of fact, the naval constructor's work stood up under torpedo attack and performed its function remarkably well. It is a matter of record, that the general run of torpedoes fired during the Russo-Japanese war did far less damage than was expected of them, and a goodly number of vessels so struck were not sunk as was counted upon, but were able to get into port and be repaired.

There were ships lost to both belligerents by subaqueous attack, but the most conspicuous of these disasters were due to the violent blows of passive mines. Where the active torpedo had failed in its mission the anchored, floating mine filled the offensive gap. These mines carried larger explosive charges than the torpedoes then in service, and proved two things: First, that the naval constructor had planned well, and, second, that the automobile torpedo must needs be made a more powerful weapon if it were to fill the office intended for it.

In the Russian fleet at Port Arthur were several vessels that had been built by the French for the Russian Government. In addition to the usual compartmenting of the inter-bottom space, the French designers had reinforced the region most likely to be attacked by torpedoes by means of a caisson built of plating nearly two inches thick. The object of this caisson—assuming that the explosion of the torpedo should be sufficient to rend or rupture the plating of the inner and outer bottoms—was to provide more space in which the guncotton gases could expand and dissipate the most dangerous percentage of their remaining force. The ingenious theory of this style of construction was proved to be all that its originators claimed for it. The Russian ships so built were several times hit by Japanese mines, and, while grevlously wounded over wide areas of their under-bodies, yet the caissons remained substantially intact, and the vessels were able to return to harbor. The Russian and the Japanese battleships that were sunk by means of mines went to the bottom suddenly, because the force of the bursting mines was sufficient to detonate the neighboring magazines; but it is not believed that the vessels lost in this way had the protection of caissons immediately next to the double-bottom space.

The immediate result of the lessons taught by the Russo-Japanese war—so far as they concerned underwater attack—was a widespread realization that the automobile torpedo would need some radical modifications if it were to make good in the future. Apart from the desirability of greater speed and greater range, the most conspicuous need was the power of delivering a more damaging blow when once in contact with its target. To that end, the size of the weapon was progressively increased in order that it might carry a bigger bursting charge of guncotton in its warhead. This desideratum has been realized; but the bursting charge of the biggest of the present day automobile torpedoes is not as large as that of the mines which damaged the ships of both belligerents during that conflict.

As a matter of fact, the more recent dreadnoughts have the under-water protection of the caisson or its equivalent, and one can't help but ask, "How does the increased charge of the warhead meet the requirements of to-day?" In addition to this, armor is being added to the defense against torpedo attack, and this is placing the underwater weapon at a still further disadvantage. Its chances of spreading havoc deep enough to affect a ship's vitals are more remote relatively today than they were during the struggle between the Russians and the Japanese. It is manifest that there is a big gap in this line of attack which the Whitehead and its various kindred rivals cannot fill, and here it is that the genius of an American, Commander Cleland Davis, of the United States Navy, provides us with an answer and places the torpedo upon a new and a more formidable footing.

Commander Davis has blazed a new path in the art. He has abandoned the guncotton warhead, which has been the accepted instrument of destruction since the inception of the Whitehead, and has substituted a gun in its stead. If one will study carefully the photographs of either bursting submerged mines or exploding automobile torpedoes, the most impressive visual sign of the violence exerted will be found in the great volumes of water blown heavenward. The water has yielded more than the steel structure attacked, and the major part of the energy designed to wreck has spent itself uselessly in blowing hundreds of tons of water into the air. Commander Davis has sought to so concentrate the powers of assault in his torpedo that but little of its force should be dissipated in disturbing the surrounding water while the bulk of the energy of his weapon should remain unimpaired and centered in piercing the enemy's defenses and penetrating to the very vitals of the object of attack. Commander Davis does not discount in the slightest the truly remarkable developments which have taken place in the other departments of the automobile torpedo. Increased range, higher speed, and more precise functioning all help him toward his objective; but it is his invention which makes this underwater projectile a graver menace to the biggest and the best of fighting craft.

The Davis torpedo, recently tested in the waters of the Lower Chesapeake, carried an 8-inch gun capable of expelling an 8-inch projectile with a muzzle velocity of something like a thousand feet per second. Ordinarily, an 8-inch gun strong enough to fire a shell with this velocity would be far too big and too heavy to be placed within the permissible limits of a torpedo. We are speaking of a piece of ordinance to be fired in the open air. Now, the Davis gun, when fired, is surrounded by the sea, which, so to speak, reinforces the walls of the gun, but this is not all. The weapon is made of vanadium steel, which has a very high elastic limit, and this great strength on the part of the metal makes it possible to construct a gun of seemingly ridiculous lightness. This fact has made the new torpedo practicable.

The muzzle velocity of a thousand feet a second is quite enough to carry the projectile through a single plate of Krupp armor, something like four or five inches thick when virtually in contact with the muzzle of the gun—as would be the case with this torpedo. Now, ships are not protected under water with plating of these dimensions, and it would be a much easier task for the projectile to pass successively through a number of thinner plates even if their combined thickness were more than the limit set. The projectile fired from this new torpedo carries a bursting charge of high explosive of between 35 and 40 pounds. This charge is detonated by a delayed-action fuse, which is designed to meet the maximum requirements imposed by the best protected dreadnoughts built, building, or projected. Our illustration represents the Davis torpedo attacking a ship of the Danton type of the French navy; vessels that typify recent practice, and which have the protecting caisson that saved some of the ships of the Port Arthur fleet from sinking when they hit the Japanese mines planted outside of that port. In our picture we see the shell piercing the five opposing bulkheads of steel, passing through one of the coal bunkers, and bursting in a boiler room. We must leave to the imagination the dreadful aftermath of this attack and the destruction of a boiler charged with high-pressure steam. The same shell might have hit either farther aft or farther forward and bored its way right into a magazine or a shell room, the consequences of which would be even more appalling. The disturbed water has been occasioned by the escaping propulsive gases from the gun, which have served to tear a big rent in the outer plating of the bottom of the ship, and the liberated air from the torpedo's air flask. The surface disturbance is very modest compared with that which either a submarine mine or an automobile torpedo of the usual types would produce.

The diagram under the picture represents the Davis torpedo, and shows a longitudinal section through only that part where the gun is installed. When the weapon has been launched upon its sinister errand the little propeller at the upper side of the torpedo's nose revolves and releases the tripping rod, so that the torpedo can be discharged upon contact with its target. When the rod hits the obstruction it is driven backward and engages the trigger which first compresses a spring attached to the firing pin and then releases it so that the pin can strike the gun primer, thus setting off the propelling charge of powder which drives the shell out of the gun. As soon as the projectile hits the outside plating of a ship's bottom the fuse in the base of the shell begins to function, being set to explode the charge in the shell so many hundredths of a second after impact. During the recent tests in the Chesapeake, the projectile first pierced the target from side to side, passing through a couple of armored bulkheads en route, and then exploded in the water beyond. The second attack was against that side of the target which was further protected by a plate of three-inch steel. The shell exploded at the instant of impact, and did not pass into the target, but the structure was so damaged that it sunk shortly afterwards. The lesson of the second attack laid stress only upon the fact that the fuse was not properly timed, otherwise the shell would have entered the caisson and exploded inside, doing still more damage. This is merely a matter of refinement, and does not qualify the startling possibilities which the Davis gun-torpedo suggests. In the future, in order to safeguard ships against attack of this sort hundreds of tons more of armor must be placed upon every fighting craft, and this must add greatly to their displacement and their cost, or be provided at a sacrifice of other vital features.

The Fire Sprinkler—Plain Business Proposition

FIRE COMMISSIONER JOHNSON, of New York, says: "As a business proposition the most effective fire prevention appliances which the Fire Department can order installed mean dollars saved to the owner of the large factory or other place of business. I refer to automatic sprinklers. Fire prevention experts agree that automatic sprinklers, coupled with a device for sounding an alarm direct to fire headquarters, form the best known method for preventing destructive fires. Experience of many years shows that automatic sprinklers rarely fail to hold fire in check until the department apparatus arrives to put on the finishing touches." In two thirds of these cases the fire is completely put out by the time the department gets there.

A Typewriter Ribbon

To the Editor of the SCIENTIFIC AMERICAN:

Please allow me to suggest the following method of making typewriter ribbon.

The base of the ribbon is the so-called "seam binding," which may be obtained at any dry goods store. It is about one half inch in width, thin, and of fine texture. The white should be purchased.

Lamp-black is thoroughly incorporated with castor oil by grinding in a mortar. This is brought to the consistency of thin paint with alcohol. The ink is applied with a cloth or brush. Oil-soluble colors may be used instead of lamp-black.

Lincoln, Ill. C. C. KIPLINGER.

Gyroscopic Action in Aeroplanes

To the Editor of the SCIENTIFIC AMERICAN:

With all due deference to Mr. Jerwan's experiences (as related in Correspondence, April 20th) it seems rather peculiar that simply because a gyroscope is in an aeroplane it should defy the laws of nature.

The Blériot machine of which he speaks would naturally circle in whichever direction it is started, because the center of gravity is behind the wheels, so that the centrifugal force throws the tail out. It might be started in either direction in many ways, such as a side gust, untrue wheels, or a slight turn of the rudder. It might be started to the left (with right-hand propeller) by the drag of the torque loaded wheel or gyroscopic action *while the tail was rising*. The latter would be momentary, and after the tail had risen it would tend to make the machine travel straight rather than circle.

Politics and Good Roads

To the Editor of the SCIENTIFIC AMERICAN:

I have read with interest your article in the SCIENTIFIC AMERICAN of May 11th, 1912, on road conservation. During the last six years I have traveled over many miles of roads in nearly all the Eastern States, and have watched with a great deal of interest the great increase in road building.

It is a delight to travel over a new State road during the first year of its life. The second year the delight is considerably less. The third year you are tempted to take to the open fields, so terrible is the going.

By this time the road needs rebuilding in most cases, and this means a fat contract.

To me this has always been the explanation of why no attempt is ever made to preserve the roads.

The original contract usually goes to some favored politician. The sole scheme being to get all the profit or graft possible, the construction suffers. I know personally of one instance where an engineer insisted that a politician-contractor comply with the conditions of his contract, and was immediately transferred to another part of the State by a complacent State Department.

The quicker this road wears out, the quicker the politician gets another fat job, consequently no repairs are made. Road conservation is therefore a joke. A large part of the taxpayers' $50,000,000 goes to build up local political fences, and faulty roads which two or three years later require at least another $25,000,000 for rebuilding.

It all means prosperity to the politician-contractor.

Brooklyn, N. Y. H. GRATTAN.

[There can be no doubt that our correspondent's contention is correct. Not until road building and road maintenance are placed upon the same sound business basis that underlies every well-conducted industrial enterprise, is it likely that we shall have roads that are good, not simply for this year and perhaps next, but roads that will be good generations hence.—EDITOR.]

"The Digestion of a New-born Infant"

To the Editor of the SCIENTIFIC AMERICAN:

In your issue of June 1st, on page 494, you have a short article under the above heading.

It is no recent discovery that new-born infants are capable of digesting food or that they possess digestive ferments. You mention of Dr. Alfred F. Hess that: "In the stomachs he found not only hydrochloric acid, as in an adult, but the two ferments pepsin and rennet." While it is true that milk requires almost no effort on the part of the digestive system, what little bit it does require is absolutely essential to the process. For instance, in all higher animals the first step in proteid digestion is accomplished by pepsin, a ferment which cannot act except in an acid medium. Hydrochloric being the kind of acid found in the stomachs of carnivora and omnivora. It is usually accompanied by small quantities of lactic acid. Rennin also is found of great importance in the digestion of milk. It is hardly correct to call it rennet, as rennet is a commercial preparation used in the manufacture of cheese, and is obtained from the stomachs of suckling calves and pigs usually.

The other ferments which you mention, namely, protease and lipase, are also necessary. The way in which lipase accomplishes the digestion of the butter fats in the milk is very interesting. To be brief, it splits them up into free fatty acids and glycerin, in which form they are capable of entering the villi. (Innumerable projections from the inner surface of the mucous membrane of the intestines, shaped like minute fingers, they are highly differentiated structures whose chief office is to absorb these digested glycerides.) Once within the villi, the synthesis of fatty acid and glycerin into fat becomes possible. Lipase is greatly aided by the bile in its work of digesting fat.

The hydrochloric acid in the stomach does not have any great effect on bacteria. In fact, none of the digestive juices possess bactericidal properties. Fortunately so, as so very rarely are bacteria harmful; the pathogenic kinds form such a small proportion of the whole.

It might not be out of the way to state that indigestion rarely occurs as a result of an insufficiency of digestive juices, but as a result of too concentrated foods; thus failing to distend the intestines, and so encourage peristalsis. Appropos of this, Dr. Charles E. Buck of Boston says "This condition never exists in the lower animals, who seldom suffer from intestinal troubles, because the food that they eat contains coarse particles of indigestible residue, that pass along the entire intestinal tract."

Oak Ridge, Va. A. G. INGHAM.

A Notable Lightning Stroke

To the Editor of the SCIENTIFIC AMERICAN:

On the afternoon of July 13th, a discharge of atmospheric electricity occurred in the village of Rockport, Ontario, which presented some features of unusual interest. About 6 P. M. a short and light thunder shower passed over the locality. The lightning seemed to be distant and the thunder was not loud. A single flash, however, struck a large white pine tree some seventy-five feet high, and tore the upper half into pieces, breaking off the branches, stripping the bark, and throwing one large fragment several hundred feet away into the St. Lawrence River.

From the tree the discharge apparently followed the telephone wire into a near-by house, smashing the windows, splintering the woodwork, breaking a 2-inch hole through a wire screen door (the broken wires showing traces of fusion) and, curiously enough, tearing off the metallic casters from a table. The telephone was connected with a ground wire which was attached to a window casing. This wire entirely disappeared, and only a groove in the wood was left.

Two ladies were standing near the telephone, one in the act of using it. Both received a severe shock and were temporarily stunned and benumbed, but recovered in a few hours without apparent injury. Owing to the nature of the soil and the long-continued drought, the ground connection was doubtless imperfect, which led to the damage to the house. Probably, however, it was the imperfect connection which saved the building from more serious injury.

In a building a few rods away a young man was holding a telephone receiver to his ear when the discharge occurred. He was thrown to the ground and received a severe nervous shock from which he did not recover for several days. This building was entirely uninjured, the telephone showed no marks of fire or any other injury, and none of the bystanders felt any shock.

The interesting points about this discharge were the sudden development of a large amount of electrical energy in a very light storm, and the almost total absence of marks of fire on any of the objects or persons struck. The splintering of the enormous pine tree could well be accounted for by the instantaneous development of steam from the sap in the wood, in connection with the expansion of the air in the tissues caused by the sudden heating by the current. The broken glass was thrown outward, indicating an expansion of the air in the rooms of the house.

One of the ladies struck said she felt no pain or shock, and remembered nothing except finding herself on the floor. The young man, however, felt a severe shock at the time, and the current probably passed from the receiver at his ear down the left side of his body, as that side and arm were benumbed for several hours. It was probable that this was an induced current in the telephone wire and not the direct discharge, as this telephone was connected with an entirely different circuit from the one first mentioned.

Rockport, Ontario. AUSTIN P. NICHOLS.

Magnetic and Electrostatic Attraction and Repulsion

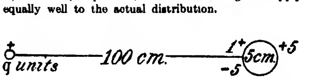
To the Editor of the SCIENTIFIC AMERICAN:

I was interested to read in your columns a short letter with reference to the force action between electric charges, and that between magnet poles, but do not exactly agree with the conclusions drawn by the writer, who apparently fails to take into consideration certain phenomena of induced electrification. In a certain sense it is true that under some conditions the question of repulsion or attraction of charged bodies depends upon the magnitudes of their charges, but only in an indirect manner, and the general law of the force action between charges still governs, even in the apparent exception noted.

To make the matter clear we might summarize the law of force action referred to. Briefly it is this Like charges repel one another and unlike charges attract one another with a force which is directly proportional to the product of the charges *and inversely proportional to the square of the distance between them.* This fact, together with the principles of induced electrification, explains the phenomenon noted by your contributor, namely, that if a body having a sufficiently great charge is brought near enough to another body having a charge of the same sign, attraction will result instead of repulsion, as we should expect.

When a charged body is placed in the neighborhood of another body (whether the latter be charged or uncharged) two induced charges of equal magnitude and of opposite sign are produced upon the latter, the one of like sign being the farther from the inducing charge. Since both charges are of the same magnitude, and the one of unlike sign the nearer, it follows from the law as to distances that the attraction between it and the inducing charge is always necessarily greater than the repulsion between the other charge and the inducing charge. Therefore a body originally uncharged is always attracted. If the body had originally a small charge of the same sign as the inducing charge, the body will be repelled if the distance between it and the induced charge is such that the difference in the distances of the two induced charges is small enough to make the difference between the forces on them less than the repulsion between the inducing charge and the charge originally on the body.

To make the matter concrete, suppose a body with a positive charge of q units placed at a distance of 100 centimeters from a sphere of 5 centimeters diameter, and having a positive charge of 1 unit localized at the end of the diameter nearest the first mentioned body. Suppose, further, that the induced charges are each 5 units similarly localized, one at each end of this diameter, as shown in diagram. Such a distribution is, of course, impossible, but the reasoning will apply equally well to the actual distribution.



We then have force action due to free charge of 1 unit $= 1 \times q/10{,}000$. That is repulsion $= q/10{,}000$ dynes. Similarly, the resultant force action (attraction) due to the induced charges is $5q/10{,}000 - 5q/11{,}025$ or about $5q/110{,}000$, approximately one half the repulsion. Therefore, the resultant is a repulsion. If the induced charges were to remain constant (they actually increase) as the charge q is brought up to the neighborhood of the sphere, say 5 centimeters from it, we should have Repulsion $= 1 \times q/25$ attraction $= 5q/25 - 5q/100$ Resultant $= 11q/100$ (attraction). This makes it evident that whether a physical object is attracted or repelled by a charged body is a matter of the relative distances of its charges from that body, the law as to the charges themselves still holding.

The conditions are very similar in the case of magnets. When a piece of magnetic material not manifesting poles is brought into the field of a strong magnet it develops poles, that of unlike sign being nearer the magnet pole which induced it. The laws of magnetic force action being precisely similar to those for electrostatic action, the same result follows as to attraction, namely, any unmagnetized bar of magnetic material is attracted. It may be laid down as a pretty safe rule, however, that like magnetic poles never attract one another. The polarity of a weak magnet may, however, often be reversed by bringing it into a strong field so quickly or in such a manner as to prevent its taking the position which the field of the stronger magnet demands. This has been a source of some annoyance in the case of compasses used in the laboratory by students who were careless in this respect.

To sum up definitely, it may be stated that the laws of force action always hold as between charges, or as between magnet poles. Apparent exceptions in the case of charged material bodies are due either to the characteristics of the bodies themselves or to the particular sets of magnetic or electrical constants involved. If not prevented by inertia, friction, or other means from doing so, these bodies behave in accordance with the laws as stated. M. F. THURSTON.

Quirigua—An American Town 1,400 Years Old

Glimpses of an Extinct American Civilization

By Sylvanus Griswold Morley, Acting Director Quirigua Expedition, School of American Archæology

DURING the months of February March and April the St Louis Archæological Society and the United Fruit Company maintained in the field at Quirigua Guatemala an archæological expedition the work being under the direction of the School of American Archæology

Quirigua was one of the older centers of the great Maya civilization which flourished in southern Mexico Guatemala and northern Honduras during the first fifteen centuries of the Christian era The writer believes that the occupation of this site lasted approximately from 450 to 550 A D though Maya students differ considerably on this point [1]

We have in the Western Hemisphere archæological relics of past civilizations as interesting scientifically as the ruins of Egypt Greece, and Rome Among them is Quirigua in Guatemala, some fifty miles from the Caribbean Sea Not until the present year was the systematic exploration of Quirigua begun This is the first popularly worded article on the results of the excavation that has thus far appeared The author writes from first hand knowledge inasmuch as he was a leading spirit in the work —EDITOR.

The work of the two previous seasons of the school at Quirigua 1910 and 1911 was largely of a preparatory nature In 1910 the ruins were surveyed and a reservation of 80 acres set aside which included all the more important remains The following year (1911) the dense vegetation which had overgrown the city since its abandonment in the sixth century A D was cleared away The importance of this step cannot be overestimated since the monuments were in constant danger of destruction from falling trees many of which exceeded 150 feet in height

The systematic excavation of Quirigua however was not commenced until the present year (1912) and it may be said at the outset that the finds already brought to light amply justify the continuation of the work The first place selected for excavation was the mound on the south side of the Temple Court A few preliminary trenches made at this point the year before had established the fact that this mound was the remains of a structure of very considerable importance Much sculptured stone was strewn around it on all sides and fragments of a hieroglyphic inscription including a date were recovered in the test diggings This seemed a most promising field for the inauguration of the work and a start was made here early in February From surface indications this mound appeared to be 105 feet long and 32 feet wide It rose from a platform or substructure the top of which itself was 20 feet above the general ground level

Before actual digging could commence it was first necessary to build a trestle to support a tramway by means of which the dirt could be removed A track was laid along each of the long sides of the building so that the work of clearing it could proceed from both sides at the same time As excavation proceeded, the ground plan of this once imposing structure, as well as its nature and use, gradually unfolded themselves.

It was symmetrical in ground plan and contained seven rooms. (See Fig 6, where a map of this building Structure 1 is shown) Entrance to these was gained by three wide doorways—10 feet wide each—in the north façade, which gave into chambers 2, 4 and 6, respectively The remaining rooms were entered from chambers 2 4 and 6, chamber 1 from chamber 2, chambers 3 and 5 from chamber 4, and chamber 7 from chamber 6. Three wide exterior doorways appear in Fig 2, which shows Structure 1 rising from the terrace at the back

These doorways were of great interest. The wall through which they pass is 8 feet in thickness, and the floors of chambers 2, 4 and 6 were in each case 2 feet higher than the floors of the doorways leading into them This 2 feet rise was effected by a single step, the front or face of which in each case presented a band of hieroglyphs. (See Fig 3, where the doorway leading into chamber 4 is shown) The band of hieroglyphics, against which the pick is leaning, is the top course of this 2 foot step, and, as appears in the figure, projects slightly beyond the courses below it Chamber 4, but partially excavated, appears in the background These three wide doorways with their hieroglyphic steps give to this building, even in its desolation, a rare touch of dignity

The floors of the interior rooms chambers 1, 3, 5, and 7 are 18 inches above the floors of chambers 2, 4, and 6, from which they are respectively entered

The rooms of this building average twelve feet in length, and are about half as wide. Although the ceilings have in every case fallen, their original height may be very clearly estimated at about 10 feet. Floors, walls and ceilings were covered with a hard, white lime plaster which still adheres in many places. No traces of wall paintings were found, though their absence may well have been due to the excessive rainfall—over 100 inches annually—to which this region is subjected, rather than to the failure of the ancients to have thus decorated their walls.

Along the back (south) wall of chambers 2, 4 and 6, there were low shelves, about 4 inches wide and a foot in height. (See Fig. 4, where chamber 2 is shown.) Note the shelf running across the back wall These shelves were covered with the same white lime plaster as the rest of the interiors In no case was any object found standing on them. In chamber 2, however, the fragments of a fine fluted bowl were found on the floor just against the back wall, and the bowl of which these were the parts probably stood on the shelf above, having been knocked off and broken when the roof fell in. Chambers 1, 3, 4, 6, and 7 yielded absolutely

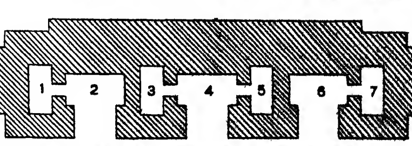

Fig 6.—Plan of Structure 1 with the chambers numbered.

[1] Various correlations of Maya and Christian chronology have been proposed from time to time Don Pio Perez Prof Eduard Seler Mr C P Bowditch and Mr J T Goodman each having advanced a different plan though most unfortunately no two of these agree The correlation proposed by the writer and his reason for adopting it will be found in Papers of the School of American Archæology No 11 Sylvanus Griswold Morley

[illegible] and chamber 2 only the fluted [illegible] been mentioned. Indeed, the only room in the entire structure which was at all rich in its yield of specimens was chamber 5, just off of chamber 4. This room contained two very fine flint spear points, as well as a dozen or more pieces of pottery.

In the back wall of chamber 4—the middle room of the building—at a height of 5½ feet above the floor, were tenoned the three stone heads shown in the bottom row of Fig. 5. When the roof of this room fell in, the tenons attaching these heads to the wall were broken, and the heads themselves fell to the floor, where they were uncovered during the excavation of the room. Two similar heads were found on the floor of chamber 6 and the broken butts of the tenons which had held them in the wall were still in position when this room was cleaned out.

When Structure 1 was completely excavated it became apparent that it had been a temple rather than a palace or dwelling type of structure. Several different facts pointed to this conclusion. In the first place, the location of the building, on a high terrace, which occupied one whole side of the Temple Court, indicated its importance, while the perfect symmetry of its ground plan—an almost universal characteristic of Maya temples[1]—strongly pointed to a building devoted to religious rather than to civil purposes.

Again, the fact that chamber 4, the middle room of the structure, was differentiated by its decoration from the other rooms—i. e., in having three heads tenoned into its back wall—seemed to mark it as the sanctuary proper, while the finding of a dozen or more bowls in an adjoining room, chamber 5, may well be explained on the ground that these vessels had been used in the temple service. The identification of this structure as a temple is further confirmed by certain of its architectural details. The only three entrances by means of which this building can be entered give into the only three rooms which have low shelves running across their back walls. These low shelves are admirably fitted both in character and position for the offering of sacrifices. Indeed, in chambers 4 and 6 it would seem as though the heads which were originally tenoned in their back walls may have represented the very deities to whom the sacrifices were offered. The width of the doorways giving into these three "shelf" or altar rooms is such—i. e., 10 feet—as to make the whole of their front sides open in each case, so that worshipers standing in the broad thresholds could easily see all that went on in the sanctuaries above and before them. The adjoining room or rooms with which each of these three sanctuaries is provided, afforded readily accessible places for the storage of ceremonial objects and religious paraphernalia, as well as convenient rooms in which officiating priests could clothe themselves. On the whole, the religious character of Structure 1 can hardly be doubted.

Before discussing the hieroglyphic inscriptions on the steps in the three above-mentioned doorways, it is first necessary to add a word concerning the exterior of this building. In common with almost all Maya structures the façade was divided into two halves by a medial cornice, which ran around the entire building about half way up the façade. In Structure 1 this medial cornice was composed of a band of hieroglyphics. (See Fig. 1, where the northeastern end of Structure 1 is shown with the hieroglyphic cornice restored to its original position.) The inscription began at the northeastern corner of the building, i. e., the corner shown in the above figure, and continued across the front and thence around to the starting point again. This cornice unfortunately was not in place at any point, but the writer was able to restore its first 18 hieroglyphics to their original positions, as appears in Fig 1.

So far as deciphered, this inscription records the date 9.19.0.0.0 9 Ahau 18 Mol of Maya chronology; that is the day 9 Ahau 18 Mol, the closing day of the nineteenth division or katun of cycle 9.

The katun was a Maya time period, which contained 7,200 days, and 20 katuns composed one cycle. We see here then, that when Structure 1 was dedicated, i. e., 9.19.0.0.0 9 Ahau 18 Mol, a cycle was very nearly at its close, since one more katun added to the 19 here recorded made 20 katuns or another cycle. This was indeed the case, for the next katun after the one here recorded ushered in cycle 10 of Maya chronology, i. e., the date 10.0.0.0.0 7 Ahau 18 Zip.

Passing now to a consideration of the texts in the three doorways; it will be found that the inscription in the eastern doorway opens with the date 9 Ahau 18 Xul. No record of the exact position of this date, that is its corresponding cycle or katun, etc., is recorded in this text, and to find its proper place in Maya chronology it is necessary to pass over to the inscription in the middle doorway. Here there are recorded 40 days, written in Maya notation as two periods of the second order, i. e., as two units, thus 2.0. Following this number occurs the date 9 Ahau 18 Mol, the same as appeared on the outside of the building in the hieroglyphic cornice on which there was declared to be the date, 9.19.0.0.0 9 Ahau 18 Mol of Maya chronology. It is a reasonable assumption, therefore, that the date 9 Ahau 18 Mol in the middle doorway was the same date as the date 9 Ahau 18 Mol outside, or 9.19.0.0.0 9 Ahau 18 Mol. Fortunately, this important point is not left open to conjecture; since in the text in the western doorway the end of katun 19 is explicitly recorded. Moreover, having established the position of this latter date, the date 9 Ahau 18 Xul in the eastern doorway may be reckoned from it, by means of the 40 days which are declared to have elapsed between the two.

The dates on Structure 1, therefore, may be summarized as follows:

Step in Eastern Doorway . .	(9.18.19.16.0)[3]	9 Ahau 18 Xul.
Step in Middle Doorway . .	2.0[4]	
	(9.19.0.0.0)	9 Ahau 18 Mol.
Step in Western Doorway	End of Katun 19	
Hieroglyphic Cornice .	9.19.0.0.0	9 Ahau 18 Mol

Although the greater part of this inscription yet remains an enigma, the chronological part as given above, may be accepted as final. Indeed, we may go a step further and analyze this part of the text somewhat as follows: Some important event occurred 40 days before the close of katun 19, at which time, and to commemorate which, Structure 1 was erected. This earlier and less important date was engraved on the step in the eastern doorway, and the distance from it to the really important date concerned here, i. e., 9 Ahau 18 Mol, the close of katun 19, was recorded in the middle doorway. In the middle and western doorways this important date is actually recorded, and it is again repeated in the most conspicuous place about this building, that is in the hieroglyphic cornice which ran around the outside.

The particular significance of this date

[1] Throughout the Maya area, symmetry in the ground plans of temple type structures is the almost invariable rule. While it is true that this symmetry of ground plan was very largely extended to dwelling type structures as well, in this latter class, however, asymmetrical ground plans are more frequent than symmetrical. Asymmetry in the ground plan of temple type structures, on the contrary, is comparatively rare, and consequently symmetry in ground plan is at least a presumptive indication that structures having it were devoted to religious uses.

[3] Matter inclosed in parentheses does not appear in the text but is indicated by the accompanying dates.

[4] In Maya numeration only 18 units of the 2d order are required to make 1 unit of the 3d order. Elsewhere however, in the 1st, 3d and 4th places, 20 units are required to make 1 unit of the order next higher.

The Heavens in August

Proper Motions and Stars; Changing Constellations; The Planets

By Henry Norris Russell, Ph.D.

As we gaze upon the familiar figures of the constellations, the thought may well impress us deeply that these same groups of stars, practically unaltered in position and brightness, showed themselves to the eyes of the builders of the Pyramids. From the standpoint of recorded history, the starry heavens are the fixed and unvarying canopy which roofs in the changing peoples and empires of earth

But will this be true if we expand our range of thought to the scale of geological time, or even to that lesser extent which embraces the probable duration of human existence upon our planet? Suppose we might leap in an instant over a hundred thousand years, and look once more at the skies Would we find then our familiar constellations? Which, if any, among them would still bear a recognizable resemblance to their present aspect?

Bold as the questions may seem to be, modern astronomy is ready with the answer. The positions of the stars have been observed for the past century with high exactness, and their motions calculated with such precision that they may be predicted (in general) for even one hundred thousand years in advance with as great accuracy as they could be plotted by the most careful eye-estimates or laid down on any star-map of ordinary size.

The accompanying illustration shows the results of such a study of the brighter stars of the constellations Scorpius and Sagittarius, which are now so conspicuous in the southern sky. The outline of Scorpius, on the right, and the "Milk Dipper" in Sagittarius on the left, can at once be recognized. The arrow attached to each star shows the direction and amount of its apparent motion in one hundred thousand years

Before this period is concluded, it is evident that the Milk Dipper will have lost all traces of its present shape, and that the whole constellation of Sagittarius will be quite unrecognizable This is what we would find in most other constellations.

Scorpius affords a very interesting exception to this general rule A few of its stars—notably Epsilon Scorpii, near the middle of the constellation—are moving at a relatively rapid rate, which will carry them almost out of the region now regarded as belonging to the Scorpion One or two at the extreme southwestern extremity are moving so slowly that they will be almost in their present places a hundred thousand years hence But the majority of the stars show a very conspicuous tendency to *keep* together in their motion. The eight bright stars in the upper part (including Antares) will be in almost exactly the same relative configuration then as now, though about a degree farther south Both components of the naked-eye double μ (shown as a single star on the diagram, next below the rapidly moving ϵ) and the conspicuous stars λ and ν at the tip of the tail, evidently share in the motion of this group, as does Theta Ophiuchi, farther to the north, and also a number of fainter stars, not shown in our figure

So many of the stars of the constellation are involved in this common "drift," that the figure of the Scorpion will still be recognizable, even after the other stars which are at present counted as belonging to it have moved clear away into other constellations, and the "head" at least should be recognizable even half a million years hence Hardly any other constellation will last as long, excepting Orion, all whose principal stars are moving even more slowly than those of Scorpius.

Such a remarkable community of motion among the stars of a well-defined region cannot possibly be the

Proper motions of stars in Scorpius and Sagittarius in one hundred thousand years.

result of chance. It requires only a glance at the diagram to convince anyone that they form a real cluster, are relatively near one another (compared with their distance from us), and are moving together in the same direction. This is in fact the most conspicuous example in the heavens of the "moving clusters" of stars, of which so much has recently been heard in the astronomical world, and its nature has been pointed out independently by several astronomers—Prof. Kapteyn, Mr. Eddington of Greenwich, and Mr. Benjamin Boss of Albany. This is not all. It is perceptible, even on the diagram, and evident from an exact study of the stars' motions, that the easternmost stars of the cluster appear to move in a direction decidedly to the east of south, while the westernmost are going almost due south. The obvious explanation is that the cluster is approaching us, and hence appearing to grow larger and spread out. This is confirmed by the spectroscopic measurements of the radial velocity of many of these stars, which (after applying certain corrections, the need for which has been shown by Prof. Campbell) show that they are all approaching one system slowly, at an average rate of about four miles per second.

This, as well as the other facts regarding this cluster, can be explained on the assumption that the stars composing it are practically at rest in space, and that their apparent motions are really due to the sun's motion. This makes it possible to calculate the distance of the group, which comes out rather more than three hundred light-years. At this distance the sun would be utterly invisible to the naked eye—fainter, in fact, than the ninth magnitude. The conspicuous stars of the cluster must, therefore, be of great brightness. All those shown on the diagram exceed two hundred times the brightness of the sun, while most of them must give out fully five hundred times, and Antares not less than two thousand times, as much light as the ruler of our system.

The Heavens.

Our map shows the aspect of the evening sky, and requires little explanation. Scorpius and Sagittarius, of which we have been speaking, are conspicuous in the south and southwest. Above them is Ophiuchus, then Aquila, with Cygnus and Lyra overhead. Hercules, Corona, and Boötes are in the west, Draco and Ursa Major in the northwest, and Perseus and Cassiopeia in the northeast. Aries, Pisces, and a part of Cetus are on the eastern horizon, with Andromeda and Pegasus above them. Aquarius, Capricornus, and the Southern Fish in the southeast complete our survey.

The Planets.

Mercury is evening star until the 22d, and morning star after that date, but is not very well placed for observation even at the beginning of the month. At this time he sets a little after 8 P. M. and may be seen in the twilight, but by the 10th he gets too close to the sun, and too far south, to be easily seen, and remains invisible through the month.

Venus is theoretically an evening star once more, and may perhaps be seen in the latter part of the month (though she sets but a little after 7 P. M.) because of her great brightness.

Mars is still an evening star, in Leo, setting about 8 P. M. in the middle of the month, and too low in the west at dark to be easily seen.

Jupiter is in Scorpio, and comes into quadrature with the sun on the 30th. He is a splendid object in the evening sky, but sets before midnight. Saturn is on the opposite side of the heavens, in Taurus. He is in quadrature on the 27th, and rises a little before 11 P. M.

Uranus is in Capricornus, and crosses the meridian about 10 P. M. in the middle of the month. He may readily be found with the aid of the maps published in previous issues.

Neptune is in Gemini, rising about 1 A. M.

The moon is in her last quarter at 10 P. M. on August 5th, new at 2 P. M. on the 12th, in her first quarter at 11 A. M. on the 19th, and full at 2 P. M. on the 27th. She is nearest the earth on the 12th (high tides again expected) and farthest away on the 25th.

She is in conjunction with Jupiter on the 7th, Neptune on the 10th, Venus and Mercury on the 13th, Mars on the 14th, Jupiter on the 20th, and Uranus on the 24th; none of the observable approaches being close.

The Business Aspect of Synthetic Rubber

What are the Prospects of the New Discovery?

By Prof. Dr. F. W. Hinrichsen, of the Koenigliches Material-Pruefungsamt

The author of this article recently completed for the Koenigliches Material-Pruefungsamt at Lichterfelde a very elaborate investigation of rubber. No man is better qualified than he to discuss the technical and commercial significance of the discovery of synthetic rubber made by Prof. Perkin. While the Editor does not wish either to detract from Prof. Hinrichsen's argument or to assist the stock-selling transactions of the English company formed to exploit the new discovery, it seems only fair to point out that in the prospectus of the English company it is clearly set forth that the immediate purpose is to manufacture fusel oil and acetone, and that part of the proceeds assured in this way are to be devoted to research on a factory scale upon the new rubber process.—EDITOR.

AT the great jubilee meeting of the Society of German Chemists, which took place at Freiburg im Breisgau last Whitsuntide, the attention of the general public was drawn to the question of the synthetic production of India rubber, two workers of special prominence in this field, Prof. C. Harries, of Kiel, and Dr. F. Hofmann, of Elberfeld, giving a comprehensive report, from the scientific and technical standpoint, on the present status of the problem.

Only recently Prof. Perkin, in England, has read a paper on the same subject, and has given publicity to new results of research in this field. While, however, the two German investigators mentioned above were very guarded and skeptical in their expressions relating to the future of synthetic caoutchouc, and regarded the time when synthetic rubber will appear upon the market as still far off, the lecture of the English chemist was more optimistic. The result was that a company with $2,500,000 was immediately founded, which counts among its board of directors no less a chemical authority than Sir William Ramsay, while Sir William Tilden has been retained as consulting chemist. Nevertheless, the opening of the list for subscriptions for shares, so far as we can judge from report, seems to have been a comparative failure, only a very small amount of capital having been sunk in the new foundation. The conservatism displayed in this case by the English public would seem to be entirely justified, for, upon critical examination, it is found that even the new results communicated by Prof. Perkin do not by any means justify the hope that any considerable quantities of synthetic caoutchouc will be produced in the near future.

From the scientific standpoint, the question of caoutchouc synthesis is clear at the present time. It is well known that caoutchouc is formed from isoprene, a compound of carbon and hydrogen, obtained as a mobile, colorless liquid of low boiling point (35 deg. Cent.), for example on heating caoutchouc itself or turpentine. As was first shown by Hofmann, rubber-like bodies are also obtainable from other compounds of carbon and hydrogen besides isoprene, which, however, must have a somewhat similar chemical constitution. Among them may be mentioned the hydrocarbon butadiene. The transformation of such compounds into caoutchouc can be effected either by simply heating under pressure with or without the addition of other substances (Hofmann) or by the influence of small quantities of metallic sodium (Harries); the products obtained differ entirely in their properties, according to the nature of the initial material employed and the conditions of transformation.

In order that synthetic rubber may be capable of competing successfully with the natural product, it must be equal to it in technical use and must be at least as cheap to manufacture.

As regards the first question, there can hardly be any doubt that in the course of time it will be possible to produce rubber by artificial means which will be equal or even superior to natural rubber in technical use. We have not, however, as yet arrived at this stage.

The price of synthetic rubber, on the other hand, depends, in the first place, on the cost of production of the initial material, isoprene, and allied hydrocarbons. Here also it can hardly be doubted that before very long processes will be found which will yield these substances more cheaply than methods known hitherto. At the present time, however, there is no such method known for isoprene, the parent substance of natural rubber. The problem is rendered particularly difficult through the fact that the substances employed must be specially pure. Most of the processes proposed hitherto do not yield a pure isoprene, but mixtures of different hydrocarbons of similar constitution. Hofmann himself, in the preparation of pure isoprene, starts from a constituent of coal tar, namely, cresol; but in this process also, so far as can be judged at the present, the cost of production is considerably greater than for natural rubber.

But even if it should be possible to prepare sufficient quantities of isoprene at a sufficiently low cost, the difficulties of the problem, as Hofmann has pointed out, only begin, for the yields are comparatively small in all methods of this kind. Consequently, in technical production on a large scale, such as is implied in case serious competition with the natural product should be contemplated, such enormous quantities of by-products are obtained, that their disposal or utilization would probably present a more difficult problem from the economical and technical point of view than manufacture of the caoutchouc itself. How is it in this regard with the new process communicated by Prof. Hofmann, and so hastily made the basis of financial operations? The principle of the new method of producing synthetic caoutchouc depends, on the one hand, on the cheap production of hydrocarbons which can be used as initial materials for rubber; on the other hand, on the acceleration of the conversion of these hydrocarbons into rubber-like substances. Prof. Fernbach, of the Pasteur Institute in Paris, has shown that starch (obtained from potatoes or maize) can be converted by means of yeast-like ferments into a mixture of fusel oil and acetone. From these compounds, the hydrocarbons required as raw material for the caoutchouc can be produced by suitable chemical transformation. The transformation of these substances into rubber-like bodies is effected by means of metallic sodium; that is to say, by the same means as discovered and used independently by Harries. According to Perkin's communication, this method was discovered and made the subject of patent application by Matthews half a year before Harries, though no publication was made of the fact. It must, therefore, be admitted that the priority of invention belongs to Matthews.

The use of starch as the initial material is alluring at first sight, owing to its low price. When, however, we examine the new process a little more closely, we cannot quite suppress doubts as to its financial soundness. An inquiry addressed to the highly reputed *India Rubber Journal* of London, regarding yields obtained in the several stages of the process, brought the following information. By Fernbach's process there is obtained from starch 42 per cent to 48 per cent crude fusel oil. The starch content of potatoes or maize is about 60 per cent. The "fusel oil" itself is said to contain only about two-thirds of true fusel oil, the rest being acetone and other compounds. Furthermore, the fusel oil gives a yield of 40 per cent to 50 per cent of isoprene, which latter is converted without loss into rubber. According to calculations which the above-mentioned English technical journal made, 100 tons of starch will be required for the production of 1 ton of synthetic caoutchouc in this way. From this it follows that only about 1 per cent yield, figured on the starch, is finally obtained, while 99 per cent of the latter goes into by-products. For the production of a quantity of synthetic rubber corresponding to the present world's consumption (about 74,000 tons), such an immense surface would have to be planted with potatoes that the ground now occupied by rubber plantations would represent only a small fraction of this.

That such a process as this cannot be very practicable is obvious. Added to this is the fact that the proof is still owing that the material obtained by the English process fulfills the technical conditions.

As has been shown by Harries, artificial rubbers obtained by means of metallic sodium differ chemically from natural rubber. It is, therefore, not by any means probable, *à priori*, that the new products will be found equal in their mechanical and physical properties to natural rubber. The situation is rendered still more difficult through the fact that the chief constituent of the product obtained by Fernbach's process is so-called butyl alcohol, which, on further treatment, does not yield isoprene, the parent substance of natural caoutchouc, but butadiene, which has already been referred to. We may, therefore, expect that the English process will yield substances differing materially in their properties from natural rubber. In any case, their technical usefulness and value is still awaiting proof. On this point there is practically no evidence available. The invention is still in the laboratory stage. As we read in the *India Rubber Journal*, there have hitherto not been prepared more than one or two pounds of synthetic rubber by the newly described process.

There is, therefore, no doubt that the formation of the company is premature. Synthetic rubber will certainly come, and will claim its place upon the world's market, not suddenly, however, at one blow, but gradually. Even then it is not probable that it will ever completely displace the natural product, especially the plantation rubber. It is much more likely that some sort of equilibrium will be struck, similar to that which now exists with regard to artificial and natural silk. In the field of technical progress, the law of inertia rules as in other domains.

The Increasing Temperature of the World

A PROPHECY of what is claimed by many to be the increasing temperature of the earth and an explanation of the recent prevalence of hot summers is found in a volume written by C. R. Van Hise, president of the University of Wisconsin, and published in 1904 by the United States Geological Survey. In this book (A Treatise on Metamorphism) Prof. Van Hise pointed out that the enormous burning of coal by man must steadily vitiate the air by the discharge of carbon dioxide, and that this vitiation must bring about a marked increase in the temperature of the globe. He says (pages 455-465):

In 1899 the amount of coal mined and oxidized amounted to 728,367,454 metric tons. At the beginning of the last decade of the nineteenth century, 1890, the production was only 511,518,358 metric tons. This shows how rapid the increase in the use of coal has been, and therefore a combustion of 1,000,000,000 metric tons a year is probably very conservative as the estimated average for the present century. Taking 1,000,000,000 metric tons as the amount of coal oxidized per annum for the future, and supposing the amount of carbon in this coal to average 80 per cent, the quantity of carbon which passes into the atmosphere would be 2,933,333,000 metric tons per annum. This is 0.1233 per cent of the total amount of carbon at present in the atmosphere. If this rate of consumption of coal were continued 812 years the amount of carbon in the atmosphere would be doubled.

"It therefore appears probable that within a comparatively short time in the future, as compared with a single geological period, or even an epoch, the amount of carbon in one of its great reservoirs, the atmosphere, will be increased to an important extent. From this fact, various geological consequences are likely to follow. One of the most important of these is a higher average temperature for the globe. According to Arrhenius, if the carbon dioxide is increased 2.5 to 3 times its present value, the temperature in the Arctic regions must rise 8 deg. to 9 deg. Cent. (14 deg. to 15 deg. Fahr.) and produce a climate as mild as that of the Eocene period. According to the above computation, the carbon would be increased by the oxidation of coal alone to three times its present amount in one thousand six hundred and twenty-four years.

"A further consequence which would follow from an increase in the amount of carbon in the atmosphere and the warmer climate would be a much more abundant and widespread vegetation, and more vegetation means that when oxidized more carbon dioxide will be concentrated in the soil, and this concentration will lead to an acceleration in the rate of carbonation. Furthermore, the increase in average temperature of the globe will accelerate all other chemical reactions of the belt of weathering. It therefore appears probable that the artificial oxidation of coal will result in some of the most profound and far-reaching geological consequences which are due to the agency of man."

Since this was written the world's annual consumption of coal has about doubled, so that six thousand million tons of carbonic oxide are now being annually discharged into the atmosphere. In view of this fact, there is little wonder that Prof. Van Hise's prognostications in regard to the increased temperature should have been so swiftly verified

Curiosities of Science and Invention

READERS are invited to contribute to this department photographs of novel and curious objects, unique occurrences, and ingenious contrivances. Such as are available will be paid for promptly.

A Land and Water Cycle

A RESIDENT of Oakland, California, owns a contrivance of his own making which it is claimed will convey him over land at a rate of twenty miles per hour and on water at the rate of fifteen miles an hour. The device he calls a hydro-motorcycle. It consists of a motorcycle equipped with two canoe-shaped metal floats, each fourteen feet long and about sixteen inches wide. Each canoe is divided into three airtight compartments and is fastened on a light steel tube frame. When traveling over land, the floats are evenly balanced, as they are carried one on each side of the motorcycle. When it is desired to make a water craft of the motorcycle, the two floats are simply reversed on their hinges and clamped down by a simple device. The propeller which, when not in use, is carried behind the seat may be dropped down into the water to propel the craft. The propeller drive contains a clutch which connects the power with a 3-foot propeller shaft of ¾-inch steel. The propeller has three 12-inch blades. Steering is effected by means of two small rudders, one on each of the floats, and both connected to the handlebar of the motorcycle. The total weight of this amphibious vehicle is 425 pounds, of which 225 pounds represents the weight of the attachment.

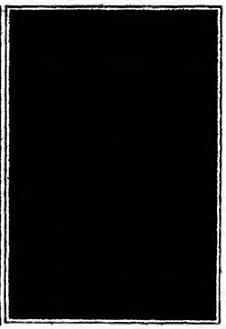
The floats folded up for land travel.

A spin on the water.

Amateur's Star Finder

AN astronomical instrument of great precision and remarkable simplicity, enabling any layman to ascertain the names of stars of constellations observed in the skies, and inversely find any star whose name or position has been given, has been designed by F. Sartorius of Göttingen. The star finder consists of a star map which may be adjusted to the geographical latitude of the place, and, a diopter pointed toward the star to be determined. Actually the device consists of an equatorial mounting, similar to that of a telescope. The main stand is a tripod provided with a spirit level for adjusting the head to horizontal position. The stand carries a graduated arc for setting the axis of the star map to the proper angle of inclination. It will be understood, of course, that the axis must be parallel to that of the earth, so that it will point to the North Pole of the heavens. The angle of inclination, therefore, is that of the latitude of the place. For instance, the latitude of New York is about 41 degrees north, consequently the axis would have to incline 41 degrees from the horizontal. A compass is provided for setting the axis in the north and south plane. The star map, then, will lie in the plane of the celestial equator. Mounted to rotate over the surface of the star map are two arms which cross each other at right angles. At the end of one of these arms the diopter is mounted, so that it may be rotated in a plane at right angles to that of the equator. The star map is provided along the circumference with graduations which indicate the right ascension of a star, also with a scale which shows the daily and monthly displacement of the heavens to be accounted for. In using the apparatus the hourly advance should also be followed continually. The diopter is swung bodily about the star map, until the arm that lies at right angles to its axis comes in contact with the star on the map whose position in the heavens it is desired to find. Then the diopter is swung to the proper angle of declination of the star as indicated by the graduations on the arm, when, on looking through the diopter, the star will fall within the field of observation. This instrument will doubtless be welcomed as an excellent means of getting an insight.

An instrument for locating and identifying stars.



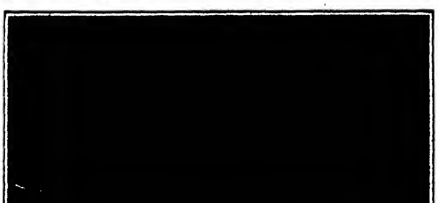
Apparatus for scaring sheep together and wolves away.

Who Owns Spitzbergen?

THIS question is often asked nowadays, in view of the remarkable development of these Arctic islands. A conference to settle the question has just been held between the governments of Russia, Sweden and Norway. A convention has been drawn up, in accordance with which Spitzbergen will be a neutral territory, open to all nations, but governed by a joint board consisting of one representative of each of the three powers above named. Taxes will be levied by the board, subject to the approval of the respective governments.

A Sheep Protector

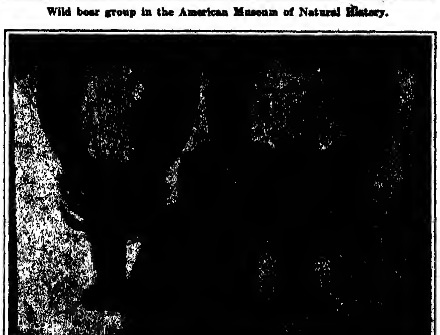
AN invention to protect sheep from the inroads of wolves, coyotes and other animals that prey upon the herds has been devised by E. C. Winchester of Thermopolis, Wyoming, and has been pronounced by sheep men of that region to be the most practical device for scaring away wild animals and keeping the sheep together at night that has yet been offered. The machine consists of an automatic gun which will shoot a blank cartridge every 30, 40 or 60 minutes, as arranged, while a bull's eye lantern is so adjusted as to revolve and flash its light in every direction. It makes more than one revolution a minute, operating by means of a coiled spring and cog-wheels, a sort of clockwork, in fact. The mechanism is inclosed in a storm and dust-proof metal case and mounted on four adjustable legs. It has a weight of 25 pounds, so that it can be carried with the sheepman's outfit with no difficulty.



Wild boar group in the American Museum of Natural History.

Wild Boar Group in Realistic Surroundings

A NOTEWORTHY wild boar group, the first of its kind to be seen in this country, has recently been placed on exhibition at the Museum of Natural History, New York. A colony of nine animals, old and young, have been realistically grouped so as to represent a habitat scene in winter in the forests of Germany, with a painted background of mountains. The group measures 9 by 15 feet. The series of fine boar skins was presented to the museum by Mr. Walter Winans, who is a noted sportsman, hunter, and horseman. The right foreground is occupied by two of the largest male boars, depicted in a fierce battle, a number of young ones are seen lying on the ground, while other still larger ones are standing in the near distance, watching the outcome of the combat. The spirited and lifelike modeling of the animals and the mounting was executed by Mr. Frederick Blaschke, the animal sculptor of the museum. The group is considered to be one of the finest and most up-to-date examples of the new plastic taxidermy.



Sixty-two pound lobster catch off the Highlands of New Jersey.

Two Record-holding Lobsters

TWO lobsters that are claimed to hold the world's record for size have just been mounted and placed on exhibition in the Museum of Natural History, New York. The larger specimen, the one on the right, weighed, when alive, 34 pounds and was nearly three feet long; the other one weighed 28 pounds. Both of these monster lobsters were caught off the Highlands of New Jersey, where they are said to have played havoc with the lobster traps, cutting holes in them and robbing them of all the bait, as their bodies were too large to get inside. Finally they were hauled up to the surface clinging to a trap. The larger specimen showed many scars, evidently from savage combats. The length of its life is estimated to have been fifty years as the average age of a ten or twelve-inch lobster is thirty years. The sea is a very poor nursery, and the best authorities figure the rate of survival in the lobster as about 2 in 30,000 eggs. Owing to over-fishing and illegal destruction of the egg-bearing females, etc., large lobsters are fast disappearing. Out of a catch of 1,000 in a recent Government experiment in New England, only 25 were found to be 13 and 14 inches long. Their ultimate extinction in the near future, it is thought by fishery experts, can be prevented, only by artificial propagation, which has been so successfully demonstrated at the Rhode Island hatchery at Wickford.

Inventions New and Interesting

Simple Patent Law; Patent Office News; Notes on Trademarks

Gaging the Cultivated Blueberry

WHILE the New England blueberry is justly famous, its systematic cultivation, until recently, has been neglected, largely through the belief that it was impossible.

The large bushes in the grounds of the Smithsonian Institution at Washington are probably more than fifty years old, and many such bushes in the Arnold Arboretum near Boston demonstrate the fallacy of the idea that the blueberry cannot be transplanted and cultivated.

Some years ago Dr. Frederick D. Coville, botanist in charge of Taxonomic and Range Investigations of the Department of Agriculture, started upon a series of investigations of the culture of the berries, which has continued to the present time with somewhat remarkable results. Proceeding with the idea that previous failures along the same line had been due to a misunderstanding of the soil requirements of the blueberry, which are radically different from those of our common cultivated plants, the Doctor, whose interest in the subject was attracted as far back as 1906, has made a careful study of the soil requirements with important results. It is evident from a consideration of what he has accomplished, as fully set out in a bulletin of the Bureau of Plant Industry of the Department of Agriculture, that the problem has been practically solved. As each advance in the arts and sciences creates a new condition or conditions, and these make demands upon the creative faculties, the Doctor found it necessary to devise a gage. This huckleberryometer, or blueberry gage, as it is more prosaically known in the department, is used for measuring the berries and in noting the progress of the cultivation. The possibility of culture has not only been demonstrated but the size development as well. Starting with a normal size of the opening No. 11 of the gage, the berries have been developed to size No. 15 and doubtless a further cultivation will result in a much larger size, the flavor and fruitiness of the berry being improved, rather than impaired, by the cultivation.

Some Interesting Toys

TOYS, especially toys in the form of dolls, are interesting to most people, and we sometimes find a toy that combines the utilitarian with the amusing. Thus Mary L. Rusk of New York city has patented a water bottle, No. 1,026,460, in which is combined a hot water bag and a cover in the form of a doll, the dress of the doll extending over the hot water bottle. By this construction, as the patentee expresses it, there is provided a hot fluid container which by reason of its appearance will be attractive to a child so that a child will permit it to be placed near it. Thus the child in taking the doll to bed with it will also have a bed warmer at the same time.

J. G. Hanley of London, England, has patented, No. 1,028,068, a toy which is shown in the resemblance of an ape and it is formed of a bag of felt, cloth or other suitable material and the lips or jaws are flexible, so that they may be manipulated by the hand to produce a grotesque and realistic effect.

Another toy has been patented, No. 1,025,909, to F. W. Fiegel. It includes a stationary picture card which has an opening in it and within the opening is arranged a contortive diaphragm which may be of sheet rubber and contains a portion of a figure such as the back and shoulders of a man, while the complementary arm portions of the figure are upon the stationary card, so that the contortive portion in the opening of the fixed card can be manipulated to produce an effect similar to that of working the muscles of the back.

A Tablet Sorting, Counting and Filling Machine

By the English Correspondent of the Scientific American

THE increasing popularity of medicinal preparations in a compressed tablet form has resulted in the evolution of an ingenious apparatus for sorting, counting and packing these preparations, which is shown in the accompanying illustration. The machine is the invention of Mr. Eduard Naumann, of Göthen, Anhalt, Germany, and has been in operation in one of the largest Berlin manufactories for several months past with complete success. The tablets are poured into a trough-like hopper, which is fitted with a specially constructed roller for the purpose of cutting off the supply and which permits a certain number of the pellets to be carried on to an agitator which sifts off the adhesive powder. The tablets are then carried forward automatically on to a grid where the imperfect tabloids are rejected.

Medical tablet sorting, sifting, counting and filling machine.

The pellets are now moved forward to the counting mechanism where, by means of a peculiar movement, the required number to enter the bottle or box are counted off and emptied into the receptacle. The counting device can be altered so that any number of pellets as desired may be passed into the vessel. A short pause is then made to allow the charged bottle to be removed, and an empty receptacle substituted at the mouth of the machine.

The apparatus can be worked either by motor power or by hand. It has been found to be thoroughly reliable, exact, and efficient. In a working day of seven hours some 200,000 tablets can be sorted, sifted, counted, and charged into boxes or bottles.

Firing Submarine Mines by Wireless Telegraphy

DR. BRANLY, the well-known French scientist, has been engaged for some time past upon various kinds of wireless distant control apparatus. He has already devised some very successful instruments for steering torpedoes, firing submarine mines, lighting lamps and carrying out a large number of operations from a distant post by sending out suitable wave signals as in wireless telegraphy. More recently he has brought out the apparatus which we illustrate here, and it is intended to protect the distant control devices against the action of continuous streams of sparks such as the enemy might send out in time of war. Not only does it prevent the continuous sparks from having any action upon the apparatus, in the case of firing a submarine mine, for instance, but should the sparks cease even for a short time, the home operator can now send out a special signal which will fire the mine. The enemy, on the other hand, will be powerless to carry out any operation of the kind. Dr. Branly's protecting device consists of a horizontal disk moved by clockwork and is kept constantly in rotation, first to the right and then to the left, by means of electro-magnets which are acted upon by distant waves. The rotation of the disk causes a series of electric contacts. The whole is so combined that when continuous sparks are sent out, the disk does nothing but rotate forward and back under this action. Should these disturbing sparks cease, the operator has time to send out certain spark signals, which act upon the disk and its electric contacts in such a way that the mine is fired. These signals are combined in such way that they are known only to the operator. In the present apparatus, the waves are received by a new type of coherer illustrated in Fig. 1. It is a modified form of Dr. Branly's tripod coherer, and is made up of a polished steel cylinder, *A*, at the lower part. It is fitted on an upright support and from this three arms, *B*, hang down by means of pivots. The arms carry well rounded steel projections which bear lightly upon the cylinder so as to make the coherer contact. One wire, *C*, comes in at the top and the second wire, *D*, is connected to the steel cylinder through the base, *M*. The whole is inclosed in a vacuum chamber in order to protect the coherer from the action of the air, and by passing electric sparks in the upper part of the chamber it can be seen whether the vacuum is in good condition. Fig. 2 shows an automatic device for replacing the operator in order to send out signals for firing the mine at stated intervals. A cam works upon a rotating disk for this purpose, and the signals can be varied by changing the notches upon the disk.

Fig. 1.—Receiving instrument.

Fig. 2.—Apparatus for firing the mines at stated intervals.

A Typewriter Which Corrects and Manifolds

MANY suggestions for improving the typewriter have been made, but nobody seems to have gone so far as to expect a typewriter to correct any defective manuscript, producing a faultless document without any trace of correction in any number of copies. This is, however, what a German inventor, Mr. Oswald Poppe, of Gera, has achieved. His invention has been patented and a working model constructed.

The apparatus forms the table of an ordinary typewriter with which it may be so connected as to allow of its being dismounted at any moment. Whenever the typewriter has produced a defective manuscript the new apparatus is called upon to correct it. If any word or clause is to be eliminated, a special key is struck at the points corresponding with the beginning and end respectively of these passages. If, on the other hand, any groups of words are to be inserted a similar key is struck at the point of the manuscript where the insertion is to be made. The words to be inserted are then written at the end of the manuscript or on a paper tape placed underneath, a correcting key being again pressed down before as well as behind these words. The defective and corrected manuscript having then been removed, a new sheet of paper is put on the roll, after which a spring is wound up or some other motive force applied. The typewriter now prepares automatically a new faultless manuscript at high speed where there are no gaps, the lines being divided automatically at the end of syllables. The typewriter can thus be allowed to continue its work, producing any number of identical manuscripts, and inscribing, if required, automatically, a different address on every copy. The manuscripts thus obtained are not distinguished in any way from hand-type documents. The output of the machine can, of course, be multiplied by producing carbon copies.

The apparatus achieves this result by producing simultaneously with the manuscript a small pattern of plain paper which is about the same size. Each letter is marked in this pattern by two or three neat holes arranged in lines, which allow the letter to be reproduced on the keyboard. Leaves of patterns can be filed for reference or later reproduction.

The same principle can, of course, be applied to type-setting machines.

A Money-washing Machine

THE United States Government recently installed in the Treasury Department for experimental purposes, the machine for renovating bank notes and other bills recently described in these columns. The machine is about fifteen feet long and includes flexible belts moving face to face and properly manipulated to secure a scrubbing action upon the bills. The bills travel a distance of from 60 to 70 feet in passing through the machine and in such course pass through a washing solution, a germicide mixture and a starching or stiffening preparation, and are finally ironed and discharged in appearance and crispness practically new bills. The cost of producing a thousand bills is nearly fifteen dollars, while it is estimated that the cost of renovating bills by the machine in the manner described will not exceed in the neighborhood of fifty cents per thousand.

The Trade-mark as a Business Asset

By W. E. Woodward

[*THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer; that it is a symbol of good will, a tangible asset with a determinable money value, that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.*

The following is the fourth of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

Analysis of the Requirements for Registration.—IV.

(*Continued from page 88, July 27th, 1912.*)

Great care should be taken by an applicant for registration of a trade-mark, or his attorney, to avoid conflict with a trade-mark that is already registered or already in use (even if not registered) provided that it is applied to the same class of merchandise as that of the applicant. Lack of caution in this respect has caused interminable annoyance and litigation, with consequent financial loss.

In considering the question of conflicting marks, the Patent Office and the Federal courts hold that the test of similarity is whether the marks are sufficiently alike in appearance or wording, or sound, to mislead the average individual. The word "Autola," as a trade-mark for cigars, was held not registrable, owing to a prior registration of the word "Auto-do" for the same class of merchandise. In this instance, registration was refused on the basis of resemblance in sound as well as in appearance. "Lady Lee" having been registered as a trade-mark for shoes, "Lady Like" was refused registration in the same class. "Certosa," as a mark for a brand of flour, sufficiently resembled "Ceresota"—already registered—to cause its rejection. "Powellton" failed registration as a trade-mark for coal, on the ground that another company's coal already bore the registered mark "Powell's Run." "Soda-foam" was considered close enough in resemblance to "Sea Foam" (already registered in the same class) to cause its rejection. "Uno," having been registered as a trade-mark for a medicine, an application for the registration of "Ino" in the same class was refused.

Registration is refused a trade-mark when it consists of words describing a symbolic or pictorial device which has already been registered; or *vice versa*, when the wording has been registered first, registration for the symbol is refused. For instance, the Patent Office has held that a trade-mark consisting of a conventional representation of a bouquet of flowers is identical in meaning with another mark consisting of the word "Bouquet," applied to the same class of merchandise. In either case, the goods would be called "Bouquet Brand."

Agreement among owners of conflicting marks is not recognized by the Patent Office. An interesting example of this occurred in the attempt to register the word "Nayassett." The word "Nassao" had already been registered for the same class of goods, and the registration of "Nayassett" was refused on the ground of similarity. Soon afterward, the owner of the "Nayassett" mark made new application, accompanied by the formal consent of the owners of the "Nassao" mark. The Commissioner of Patents held that the law did not provide for agreement between owners of conflicting marks, and the registration of "Nayassett" was refused accordingly.

About two years ago a manufacturer in a middle Western city became interested in a new metal polish and decided to put it on the market. After long consultation with advertising men and salesmen, a name was selected. This name was suggestive and short, with a snap to it that made it stick in the memory. Thousands of labels were ordered and packages of the article were given to the traveling salesmen of the concern to be used in getting orders from retailers. Booklets and literature had been written and mailed, and the business was beginning to take shape when, to the surprise of the manufacturer and his associates, his application for trade-mark registration was rejected by the Patent Office for the reason that the mark had already been registered. Then followed a hasty trip to a trade-mark attorney, and a search of the Patent Office records was made. Investigation of the register showed that the same name had been registered by an Eastern concern for a metal polish some years ago. About this time, a letter arrived from the attorney of the Eastern firm, with a statement to the effect that the owner of the trade-mark considered this unauthorized use of the mark an infringement and intended to take legal action in the matter. A month or two was spent in trying to make some arrangement with the Eastern concern, with the final result that the trade-mark had to be dropped and something new devised. In this case a full year was lost, and a considerable amount of money was wasted, by reason of the failure of this manufacturer to have a search made of the Patent Office records. He made the mistake of considering the matter of trade-mark registration a small detail, and trying to attend to it himself. A competent attorney would have saved his fee a thousand times over in this case.

A trade-mark consisting of the insignia of the American National Red Cross is not registrable. This prohibition is not covered by the trade-mark law, but is one of the provisions of the act of Congress incorporating the American National Red Cross (approved January 5th, 1905). This act of incorporation states that it shall not be lawful for any person or corporation to use in trade, or for purpose of advertisement, "the sign of the Red Cross" or "any insignia colored in imitation thereof," unless such person or corporation was entitled to the use of such insignia at the time of the passage of the act. This exception, which was intended to safeguard the interests of those who had long used the Red Cross sign as a trade-mark, covers the Red Cross mark of the well-known druggists' specialty house of Johnson & Johnson, the Red Cross labels used on a brand of shoes made by Krohn, Fechheimer & Co. of Cincinnati, the Red Cross mattress manufactured by a Boston concern, and a few other users of this device. The law, as it stands, is rigidly enforced in regard to all new trade-marks containing Red Cross devices. An unusual argument was made the basis of an application for registration of a label for a cough syrup, on which the emblem of the Red Cross was printed, accompanied by the words "Red Cross." When registration was refused, the applicant sought to amend the label by striking out the Red Cross emblem, while leaving the words intact. He argued that the Red Cross incorporation act prohibited only the use of the "sign of the Red Cross" and not the words. The application was rejected on the ground that it was an attempt to evade the spirit of the law.

A trade-mark is essentially an exclusive possession. When it ceases to be exclusive, it ceases to be a trade-mark, in the true sense. It is apparent, therefore, that an ordinary word, descriptive of the goods with which it is used, cannot be set aside as the exclusive property of any manufacturer, to the detriment of others producing merchandise of the same character. The wording of the law on this point is clear, and the Patent Office is strict in its interpretation. But despite this condition, many applications, destined to be rejected, are made every year for the registration of descriptive marks. We quote here a few examples of trade-marks refused registration on the ground of being descriptive:

The word "Kantleek" was refused registration as a trade-mark for a hot-water bag. The Patent Office examiner held that the word was composed of "Can't" (misspelled "Kant") and "Leak" (misspelled "Leek"), and that it was intended to convey the idea that this particular bottle could not leak. The attorney for the applicant presented an argument to the effect that this word was composed of two German words "Kant" and "Leek," that had meanings quite different from the English words with the same sounds. This contention was too subtle for the Patent Office to grasp, and registration was refused.

The word "Naphtha," used as a name for a soap with naphtha as an ingredient, was held to be descriptive and therefore not registrable as a trade-mark, to the exclusion of the goods of other manufacturers, although the owner had advertised it extensively.

"Mello," as a mark for chewing-gum, was considered descriptive, being simply a misspelling of the word "Mellow."

(*To be continued.*)

Notes for Inventors

A Cipher Typewriter.—The cipher typewriter, it is said, is coming into vogue among diplomats and business men. It is a machine by means of which a message can be written that can be read only by him for whose eyes it is intended.

Another Safety Appliance for Aeroplanes.—In a patent, No. 1,030,312, Henry Laprise of Holyoke, Mass., presents an aeroplane which is provided with a recessed top forming pockets in which collapsible floats are packed, the floats being adapted to be released from the stowage spaces and having bottom openings so that they may be filled and expanded with air from below.

A Poison-indicating Bottle.—In a patent, No 1,032,610, Emile A. Kern of West New York, New Jersey, presents a bottle for indicating poisonous contents, which bottle consists of inner and outer walls forming a chamber between them and a light-emitting compound in the chamber, which chamber is entirely closed and permanently confines the luminous compound in the chamber.

Primitive Lobster Traps.—If you have ever been in the lobster country, you will doubtless remember the traps, all alike and all made of laths. Laths are almost legal tender with the lobster catchers, and this fact makes a lath-laden derelict cast up on the shores of the lobster waters especially desirable. The traps are not especially secure, as lobsters frequently enter, eat the bait, and if given enough time, escape; and, possibly, some one acquainted with the conditions can devise a more efficient trap for the purpose.

Two Hollerith Machines.—Herman Hollerith of Garrett Park, Md., assignor to the Tabulating Machine Company, has just secured two patents, No. 1,030,304, for a registering apparatus, and No. 1,030,305, for an apparatus for use in tabulating systems. The apparatus presented in these systems is very complicated and is designed for use in the tabulating and registering processes which Mr. Hollerith has done so much to develop. It will be remembered that Mr. Hollerith was among the pioneers in this art especially in the designing of machines for use by the Census Office in its tabulating operations.

The Need of a Stripper for Crimson Clover Seed.—A botanist friend, specializing along agricultural lines, tells the writer that the small farmer needs an implement for gathering his crimson clover seed, that such seed is expensive and that, so far as he knows, there is no satisfactory device at present for gathering the seed on a comparatively small scale. The demand appears to be for a hand stripper of low cost which can be readily operated to harvest the seed without much loss. As the seed is expensive, such an implement would quickly pay for itself.

The Many Roads to Invention.—A well-known inventor, who for many years has invented along the same line and has made a great commercial success of his useful inventions, tells how he recently was led to make an important improvement in one of his machines. His young son asked him how the differential gear of his automobile worked. Wishing to give a correct explanation, he looked up the technical features of the transmission, and in doing so happened upon the very improvement he had hitherto been unable to complete, so that largely by accident he was able to produce a desired invention which had eluded him when deliberately sought.

Wanted a New Method of Curing Pork.—In a note from abroad, Consul Albert Halstead of Birmingham tells how the increasing use of pigskin and its tendency to advance in price has raised the question as to whether the great waste due to leaving the skin on bacon, ham and other pork products can be avoided. The English *Leathers Trade Review* estimates that there is a yearly loss of skins amounting to about $3,000,000 in the United Kingdom alone. The waste of skins is evidently unavoidable under present conditions; the difficulty is to find a method of curing that will prevent any loss of the meat if the rind or skin is removed.

Legal Notes

Disclosure and Priority.—In Hewitt vs. Weintraub (Mercury Vapor Lamps) the Court of Appeals of the District of Columbia, in affirming the decision of the Commissioner awarding priority to Weintraub, held that priority was properly awarded to Weintraub on the ground that the invention in issue is not disclosed in certain earlier applications of Hewitt, and said:

"Hence the appellant is here with the concurrent decisions of the tribunals of the Patent Office against him; and where this appears, as we have frequently said, we are loath to disturb such findings, especially where the invention is of a highly technical nature, such as this, unless it is clearly apparent that error has been committed."

Accounting for Profits.—The decision by the Supreme Court of the United States in Westinghouse Electric and Manufacturing Company vs. Wagner Electric and Manufacturing Company holds that where the infringer has sold or used a patented article, the plaintiff is entitled to recover all of the profits. Also that where a patent, though using old elements, gives the entire value to the combination, the plaintiff is entitled to recover all the profits; and that where profits are made by the use of an article patented as an entirety, the infringer is liable for all the profits "unless he can show—and the burden is on him to show—that a portion of them is the result of some other thing used by him."

Protecting the Flag.—Representative Cox of Ohio has introduced in the House of Representatives, a bill making the use of the flag or the coat-of-arms of the United States, or any pattern, imitation, or representation thereof, either by printing thereon or painting thereon or attaching thereto any advertisement or device for the purpose of gain or profit, or as a trade-mark or label, or the imitation or representation of the flag or the coat-of-arms of the United States for an advertisement, trade-mark, or label, a misdemeanor. The bill also provides that no copyright shall subsist in the flag or coat-of-arms or other insignia of the United States, or any simulation thereof. The bill also makes it a misdemeanor for any person to tear down, trample upon, or treat with indignity, or wantonly destroy the flag or coat-of-arms of the United States, and also provides for a fine not exceeding five hundred dollars or imprisonment not exceeding one year for violation of any of the provisions of the act.

[illegible] PATENTED INVENTIONS

These columns are open to all patentees. The notices are inserted by special arrangement with the inventors. Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN.

Pertaining to Aviation.

FLYING MACHINE.—G. E. THOMPSON, 199 Howard St., Detroit, Mich. This easily controlled and balanced flying machine is adapted to float on water by means that form a fluid cushion between the water and the machine, whereby the device may be raised from the water. The invention provides a supporting plane, and means for rarefying the air or compressing the air at either end of the plane for balancing the same.

Electrical Devices.

WIRELESS MEANS FOR CONTROLLING AEROPLANES.—C. L. VANDERBURG, R. F. D., No. 2, Box 48, Fayetteville, Ark. This inventor provides a simple device by means of which the movements of an aeroplane may be so controlled that it will respond directly to the will of the operator, thereby avoiding the necessity of carrying a passenger to manipulate it. He also provides means for effecting aeroplane operations in dropping bombs or torpedoes.

AUTOMATIC DEVICE FOR TURNING MUSIC.—C. DALMONI and J. MACABIO, 49 Grove St., New York, N. Y. Means are here provided for turning music in sheets or in book form; and the invention comprises a combination of actuating elements by which a sheet or page can be turned in either direction. The music is engaged with sufficient force to move it from one position to another, and the actuating arm is always returned to its original position when released. Means provide for preventing waste of current furnished by the source

Of Interest to Farmers.

ADJUSTABLE SCRAPER.—N D. MCCOLLUM, Gore, Ga. This improvement relates to plows and cultivators, and the aim is to provide a scraper for attachment to a plow or cultivator, and more especially designed for scraping the ground on opposite sides of the plow point and sweeping it outwardly onto the adjacent rows of plants, hills or the like

CUTTER BAR FOR MOWING MACHINES—C. FALK, R. F. D., No. 1, St. Paul, Neb. This invention provides a removable extension for the cutter bar to augment the cutting capacity of a mowing machine, and provides means for splicing the extension and main frame of the cutter bar which is simple, economical and efficient.

COTTON CHOPPER.—R. HAMILTON, P. O. Box 711, Pensacola, Fla. The machine covered by this patent employs disk cutters arranged in pairs, the disks of each pair converging toward the front, and in connection with the disks, cultivator shovels are employed at the rear of the machine; the invention resides in a novel construction and arrangement of the parts for raising, lowering and otherwise adjusting the disk cutters and the shovels. There is also comprised in the machine a novel arrangement of guide wheel and its controlling lever.

Of General Interest.

TUBE.—J. W HAWKINS, 121 Union Ave., Passaic, N. J. This tube is commonly known as a paint tube, made of tin foil or similar material, for containing paint, tooth paste and other semi-fluid substances, the tube being arranged to open by pressure from the outside to govern the outflow of the tube contents onto a palette, tooth brush, spoon or like article, and to close the tube by pressure of the contents from the inside on release of outside pressure.

RACK FOR PAPER BAGS.—C. J. TABER, Bainbridge, N Y. This rack is for use in holding paper bags of various sizes and in a manner for convenient removal of bags singly of a desired size as required by the storekeeper, and arranged to permit of placing the rack in a flat, inclined or vertical position on a counter or other support, and to allow of filling each individual holder with a bundle of bags of a size corresponding to the holder.

PROCESS FOR BLEACHING OLD PAPERS, PAPER STOCK, STRAW, ETC.—J. H MELCHERS, McCanna, N. D. An object of this invention is to provide a process by means of which the coloring matter, ink, etc., may be removed from old papers so as to make stock of pristine whiteness. Further to provide a process for bleaching paper stock in which there are iron salts.

FOLDING CROSS.—H. T. WALROW, 66 Halsey St., Astoria, Queens, N. Y. Mr. Walrow's invention relates generally to articles of jewelry intended for ornamental purposes on watch chains, and more particularly involves a folding cross. The object is to provide a folding cross which will be pleasing in its appearance and well adapted to serve as an article of adornment.

MEASURING AND BAG FILLING DEVICE.—[illegible], 178 Border St., East Boston, Mass. This apparatus measures out quantities of material and delivers the same to containers. It is particularly applicable for use in filling bags with coarse material, such as coal. Coal is often sold in small quantities, and this device permits of the delivery of such a small quantity of extra coal as may be necessary to bring the quantity in the bag up to the required weight standard.

NON REFILLABLE BOTTLE.—M. HORNSTEIN, 184 Warren St., Jersey City, N. J An object here is to provide a simple closure for the bottle The inventor attains this by constructing the neck of the bottle in two parts and by disposing a gasket at the connection between the parts, which gasket supports a float valve having a limited movement off the seat.

UMBRELLA ATTACHMENT.—T. C. FREDRIKSEN, Astoria, Ore This invention more particularly comprehends a device designed to be secured on the handle portion whereby the umbrella may be conveniently suspended from

UMBRELLA ATTACHMENT.

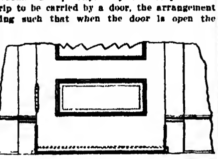
the clothing of the carrier. The device may be applied to any umbrella, and the inventor's purpose is to provide for suspending the device from the clothing when it is necessary to use the hands for other purposes, as shown in the illustration, thereby avoiding the tendency to mislay or lose such articles. The device may assume a variety of ornamental designs according to the style of handle employed

COMBINATION TRAY AND GLASS HOLDER.—J. HEAROLD, Richmond Hill, Queens, New York, N. Y. The object here is to provide a holder for use in saloons clubs, private houses and other places, and arranged for convenient attachment to a table or other support to conveniently hold a drinking glass and support cigars, cigarettes, ashes, and matches

FOUNTAIN PEN.—J. J MEAD, 390 Crescent St, Brooklyn, N Y In this patent the invention has reference to fountain pens of that type known as "self fillers" An object of the inventor is to form a fountain pen which will be quickly and easily filled without the necessity of removing the pen point

VENTILATING AND PERFUMING DEVICE.—P. KILLPATRICK, 4217 W. Kinzie St. Chicago, Ill. An object here is to provide a device by means of which pure air may be supplied evenly to the various parts of a room And further, to provide a device by means of which the natural perfumes of growing flowers may be supplied to the interior of a dwelling, hospital, or other building.

DOOR STRIP.—L J. VALENTINE, Plainview, Texas. This invention comprehends a construction adapted to be carried by a door for engagement with the floor or sill and provides a construction wherein air and wind with any particles carried thereby may be kept out of a room. The principal object is to provide a strip to be carried by a door, the arrangement being such that when the door is open the



DOOR STRIP.

strip is out of sight, coöperating with means carried by the door whereby when it is closed the strip will be moved into operative position adjacent the floor or sill. The strip is adapted to lie closely adjacent the floor when the door is closed, even though the floor be irregular or in a different plane than that intended The engraving shows a partial front view of a door with the casing therefor showing strip in operative position.

Hardware and Tools.

WEDGE.—W. WALTERS, Glendale, Wash. The object here is to povide a new form of wooden or iron wedge so constructed and reinforced that the wear and tear is taken off the metallic parts, and the stresses and strains incidental to an article of this character, are evenly and proportionally distributed over the whole surface.

CARPENTER'S GAGE.—M. B. MATHESON, P. O. Box 183, Duluth, Minn. The intention in this case is to provide a simple device for carpenters' use, and designed for quickly and accurately locating on a door the exact points at which to cut the openings for the key and knob of the lock, and the width and depth of the cuts for the hinges.

COMBINATION TOOL HOLDER.—W. L. HANE, care of Hocks & Duval, Ocala, Fla. The object of this invention is to provide a simple and inexpensive holder for use with lathe planer and shaper, wherein a single improved implement will perform the functions of three now necessary, and by means of which a great economy in time and labor is effected.

ENVELOP OPENER.—J W SINNOTT, 846 E. 146th St, Collinwood Station, Cleveland, Ohio This invention contemplates a tool having a guide slot or passage to receive the edge of the envelop to be opened with a knife or cutter located in the guide or passageway in position to engage beneath the flap as the envelop is moved along the guide or passage, or the tool is moved along the envelop

Heating and Lighting.

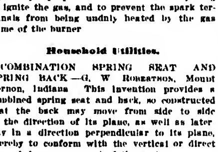
ELECTRIC GAS LIGHTER.—H D GRINNELL, Agricultural National Bk Bldg, Pittsfield, Mass. This lighter has spark terminals for convenient and quick attachment to the gas burner tip without requiring any constructive changes in the tip, at the same time directing the jump spark across the burner opening to ignite the gas, and to prevent the spark terminals from being unduly heated by the gas flame of the burner

Household Utilities.

COMBINATION SPRING SEAT AND SPRING BACK.—G. W ROBERTSON, Mount Vernon, Indiana This invention provides a combined spring seat and back, so constructed that the back may move from side to side in the direction of its plane, as well as laterally in a direction perpendicular to its plane, thereby to conform with the vertical or direct up and down movement of the seat

Machines and Mechanical Devices.

STRAIGHTENING PRESS.—J. JOHNSON, 413 Gvepp St, Bethlehem, Pa This invention straightens bars, cranks, and the like, without removing the same from their centers. Further, it arranges means for straightening the above, which utilizes the leverage action of a cam, and an even positive pressure caused by the



STRAIGHTENING PRESS FOR BARS, CRANKS, ETC

action of a screw moving the cam. Means provide for bending bars of any desired length, the means for accomplishing this being such as to accommodate bars of certain lengths without removing them from their supporting centers, and for accommodating bars of greater length than the device, by substituting auxiliary supports in place of the centers The engraving shows a fragmentary longitudinal sectional view through the structure

ANIMAL TRAP.—W A MAY, care of W H HARDEN, Quitman, Ga This is an easily cleaned mechanism wherein the entrance opening is normally open, and is closed by the entrance of the animal, and wherein other compartments are provided into which the animal may freely pass, but cannot return in order to permit the trap to automatically set itself.

MACHINE FOR MAKING STAVES.—T G MARTIN, 1029 Quincy St, Parkersburg, W. Va Mr Martin's invention is an improvement in stave machines, and has for its object the provision in a machine of this character, of new and improved means for cutting and equalizing staves, while the staves are being moved continuously through the machine

SHAFT HANGER.—G. C SPILLERS, Alexander Bldg., Tulsa, Okla. The improvement is in hangers suspended from ceiling plate or bracket; and the special feature is the adaptation of the hanger for adjustment of its movable members for the purpose of placing a shaft in different position as required to secure alignment or parallelism between different shafts.

PHOTOGRAPHIC SHUTTER.—J RICHARD, 25 Rue Mélingue, Paris, France. The invention relates to shutters for photographic apparatus and more particularly for stereoscopic cameras. The shutter is characterized essentially by the fact that the movement of the leaves of the shutter, in one direction or in both, is operated by percussion by means of a mechanical device independent of the leaves themselves.

CACULATING MACHINE.—NELSON STAFFORD, 67 Fulton St., Manhattan, N. Y., N. Y This inventor provides a machine wherein are imprinted in column form a succession of numbers, and wherein may be imprinted at will the totals of column sections, or the result of a succession of such totals; and provides means for exposing to view at will the composited number designed for addition to the column and number indicating the total of the column inclusive of the number composed for addition thereto

INTEGRATOR FOR CONVEYER BELT WEIGHING SCALES.—W P BUCHAN, Box 876 Kansas City, Mo This invention provides registering mechanism to display for record the total weight of material passed over a belt conveyer when operatively connected with the mechanism, and provides for recording accumulatively the total weight as the same is passed over the conveyer to which mechanism is attached, irrespective of rate of travel of the belt, whereby variation in the conveyer mechanism incident to load variation is instantly compensated

Prime Movers and Their Accessories.

INJECTOR.—W. H. LOCKE, care of Simms & Enslow, Thompson Pierce Bldg, Huntington, W Va The purpose here is to change the construction and action of various movable parts in order to increase the positiveness of the action of said parts and to enable the injector to be used under greater extremes of temperature of hot and cold water, as well as to increase the amount of pressure against which the injector will work

DEVICE FOR STARTING INTERNAL COMBUSTION ENGINES.—D E CROUSE, Annapolis, Md This device permits the starting of the engine through the action of a spring under tension, and the spring is restored to its original position after the engine is started. The starting of the engine is done by the movement of a rack into engagement with a pinion, with means for swinging the rack out of engagement with the pinion and causing its return to its original position, thereby permitting the pinion to turn freely with the engine shaft

Pertaining to Recreation.

ANIMATED TOY.—A GUND, Gund Mfg Co., 220 W 19th St, New York, N Y. This invention relates to wheeled toys, and its object is to provide an animated toy which simulates an animal, such as a dog, duck or the like, and when drawn over the floor moves certain members and at the same time emits sounds similar to those emitted by the animal simulated

Designs.

DESIGN FOR A BANK CHECK.—P E HASS, 51 Liberty St, New York, N Y One half of the area of this design for a bank check comprises a square of four double rings with bands to and from, in the center of which is a highly ornamental body of characters surrounding a center circle inscribed with the words Bank Safety Paper, and in the center of this ring is a U S shield and eagle

DESIGN FOR A CARPET OR A RUG.—G S. SQUIRES, 41 Union Square, New York, N. Y In this exquisitely ornamental carpet or rug the border involves the design of three bands or styles of geometrical patterns The field is flat with a heavy clustering of flowers in the corners, and a massive design for the centerpiece

DESIGN FOR A METAL PLATE.—J S LARSEN and A VALENTIN, 470 W 165th St., Manhattan,, New York, N Y This is a simple and effective ornamental design comprising a circular plate, the outer edge of which is pointed by an eight-point star, the base of whose angles joins an inside ring in whose center is a diamond. Small dots or rings are arranged around the plate.

DESIGN FOR A WATER CLOSET BOWL.—J AMIESON, care of Lambertville Pottery Co., Lambertville, N J In this simple and graceful design for a water closet bowl the distinctly original feature lies in the angular position of the inlet

DESIGN FOR A LOCKET.—C DAILEY, care of Klein & Sons, 14 Park Place, New York, N. Y In this ornamental design for a locket the little case holds a flat disk on which is pictured an upper half image of Christ, and on the reverse side that of the full figures of the Madonna and child

NOTE.—Copies of any of these patents will be furnished by the SCIENTIFIC AMERICAN for ten cents each Please state the name of the patentee, title of the invention, and date of this paper.

VI.—Shall My Boy Become an Industrial Chemist?

By Prof. H. C. Peffer, Purdue University.

*[This is the sixth of a series of articles intended to set forth fairly the business possibilities of the technical professions. The articles are prepared by men who are connected with the more important technological institutions of this country and who are for the most part prominent educators. Because these teachers have instructed hundreds of young men in the principles of engineering, they are best qualified to write upon a subject so immensely important in the future development of American manufacturing industries.—*EDITOR.*]*

THE importance of the chemist to modern industry is daily becoming more manifest, due to recognition of this fact, his sphere has extended beyond the bounds of the strictly chemical and metallurgical industries, and he is called upon to take part in numbers of operations closed to him but a few years ago.

New opportunities lie in the fact that most of our great industrial institutions, in an effort to eliminate waste, improve their processes of production, or to find new outlets for their products, are founding research laboratories, employing numbers of trained men. One such firm has 250 men on its chemical staff; others have smaller numbers, but the significant fact is that a few years ago such a thing would have been deemed unnecessary. The result will be that the competitors of these firms will in turn be obliged to resort to systematic investigation of their processes, or fall behind in the race, with the further result that skilled chemical technologists will be in increasing demand.

This field of research is of the greatest interest to the chemist, because the greatest possibilities for the individual lie in this direction, and because our industrial development depends on its intelligent prosecution. It is not to be supposed, however, that the young college or university graduate is fitted to undertake independent investigations; in order to become a successful research chemist, the theoretical knowledge gained at college or university must be supplemented and reinforced by practical experience, and the faculties of observation and independent thought developed.

Neither is research the sole end of a chemical education; our industries are in need of technically trained executives and more intelligent supervision. In these days of large scale operations, increased attention is being given to the purchase of materials under specifications as to composition. This may mean, first, the employment of more analytical chemists, but beyond this, it means that primarily the material must be manufactured up to a given standard, which marks the passing of the old "rule of thumb" executive, and the advent of one of higher degree of technical training—the Chemical Engineer.

No mention has so far been made of this newcomer, who will share the field of Industrial Chemistry with the chemist, and who is in many respects better equipped than the latter. That the importance of the chemist has not been fully appreciated, up to the present time, at least, is no doubt due to the fact that his training has not fitted him to conduct the large-scale operations necessary in a manufacturing plant; to insure the highest degree of success in Industrial Chemistry, it is necessary to be able to carry through to a practical conclusion in the plant the principles worked out in the laboratory. This means, in addition to a thorough grounding in chemistry, additional training as mechanical and electrical engineer, the combination constituting the Chemical Engineer. The question of the proper college course for this branch of engineering has been under discussion for some time, and our attention will be directed rather to a consideration of the important period comprised in the years immediately following graduation, which exercise such a strong influence on a young man's future.

The college course in Chemical Engineering has of necessity been largely theoretical, and practical experience is necessary to the finishing of the young chemical engineer; this will come by contact with practical operations throughout the remainder of his career.

It has not been found possible to crowd into the compass of a four years course all the studies which should constitute the equipment of the chemical engineer; he will be fitted on graduation to enter a subordinate position in some industrial plant, and advance step by step, as his knowledge of details and practical experience increases. Most men stop here, but in order to make the most of the possibilities open to him, the young chemical engineer should, after a few years of practical experience, spend some time at a good university in further study. The degree which he obtains may be of little use to him directly, but his practical experience will have given him such a different point of view toward his work, that he should profit more in point of efficiency from his university than from his college course.

The necessity of starting at the bottom in industrial work is a great advantage; aside from the inevitable readjustment of his ideas as to his importance in the "plan of things," a young man's apprenticeship in a subordinate position results in habits of industry and punctuality and a knowledge of details which is not to be obtained otherwise. Criticism to which men of uninterrupted college and university training are too often open from the practical standpoint is that they fail to see the advantages of starting at the bottom in industrial work. They thus miss the intimate knowledge of details which the practical man possesses, also the advantages of contact with workmen and understanding of them, as well as knowledge of what constitutes a fair day's work.

It is essential that the chemical engineer be able to handle and deal with men, and on this rock many an otherwise good man has foundered. A term in the works is therefore advisable before completing the course of study indicated.

This may appear to be quite an ambitious schedule, but, to cite a familiar instance, it is just about what a young graduate in medicine must go through before he is competent to enter upon the practice of his specialty. Great stress is laid on the proper training for the chemical engineer, because, aside from the man himself, it is the thing of greatest importance; the leaders in this field will be those who combine practical ability with high scientific attainments, and other factors being equal, the man with the best preparation will be the most efficient.

The general question as to whether a college education is necessary to success along technical lines, is one which is frequently raised, the inference being that it is possible to secure such an education otherwise than by attending college. Granting for the moment that such may be the case, it should be possible to develop from the larger number of young men in the shops and factories at least as many efficient technical men as the colleges—which is not the case.

The question is not one to be settled by academic discussion; the test is that of utility based on the efficiency of the average technical graduate, as compared with the average non-graduate. Perhaps the most competent to pass on the question are those who come most closely in contact with both classes—the heads and executives of our great industrial enterprises; these men measure in terms of results, and their verdict comes in the shape of demand that applicants for a constantly increasing list of positions shall be technical graduates. To use another familiar instance, the sales forces of most progressive firms are now largely recruited from the ranks of technical graduates, whereas a few years ago the practical man had the field largely to himself.

For the chemist or the chemical engineer a college training is a necessity. It may be possible for a bright, determined young man, employed in some line of industry, to acquire by his own efforts a limited knowledge of the chemistry of that particular

[illegible] will be [illegible] only as long as [illegible] present themselves, and [illegible] elsewhere. The day of the [illegible] man in technical lines is past; the fields of chemistry are so wide and diversified that no man, however able and industrious he may be, is able to make much headway unaided. Competent instruction and the proper equipment for experiment are needed; the college and the university, which have specialized in this department, afford the only means open to the average young man for proper instruction.

Quirigua

(Concluded from page 97.)

9.19.0.0.0 9 Ahau 18 Mol at Quirigua is, that it is the latest date yet found at this city, and indeed for that matter, one of the very latest in any of the southern Maya centers. With the coming of Cycle 10 the great southern cities rapidly declined, and only two or three of them show dates later than the close of katun 19, which is inscribed here on Structure 1 at Quirigua.

In addition to Structure 1, a low and much smaller mound, some 30 feet southwest of it, was excavated, and this proved to be a building of the dwelling type. (See Fig. 2, where Structure 2 appears in the foreground to the right.)

This latter building was perhaps of greater interest than its more imposing and pretentious neighbor on the terrace behind. To begin with, Structure 2 is older than Structure 1. Indeed, the terrace upon which the latter stands was built *around* Structure 2, covering it up to within 6 or 7 feet of its roof. Only the north side of Structure 2, that containing the doorway, was left open. (See Fig. 2.) The covering up of three sides of this building by the terrace of Structure 1, doubtless made for its preservation; and to this fortuitous circumstance alone we are indebted for the solution of several important architectural problems. Until the excavation of this building it had been a disputed point whether the treatment of the façade above the medial cornice—i. e., the upper half—had been sloping like a Mansard roof or vertical. Both methods of treatment had been found in other Maya cities, but heretofore no façades, either at Quirigua or Copan, were standing to a sufficient height to determine this important point. In Structure 2, however, enough remained to show that the upper half of the façade sloped backward. Although this same fact could not be positively established in connection with Structure 1, because of its greater demolition, nevertheless, by analogy, the writer believes that it also may be regarded as having had the upper part of its façade sloping. Probably the same may be said of all other buildings, both here and at Copan.

Structure 2 yielded more specimens than Structure 1. A number of pieces of pottery were recovered, including a very fine painted fluted vase with a grotesque human head on one side. Many mother-of-pearl beads were found, but long exposure to the moisture had rendered them crumbly and rotten. A few jade beads were also found, but they were small and in no way worthy of note. The most unique find in Structure 2 was a series of worked hematites. These were hexagonal in shape, about one sixteenth of an inch in thickness and not over one inch in width between the two points. One side was very highly polished in each case, the other being ground smooth. The edges were beautifully cut; and some of the fragments showed a round edge, as though such pieces had formed the border of some mosaic. The purpose for which these were used is unknown; and so far as the writer is aware, nothing like them has ever been found.

An interesting feature, tending perhaps to confirm the identification of Structure 2 as being of the dwelling type, was the stone hooks which were found in the walls on both sides of every doorway. These were about four and one half feet above the level of the floor in each case, and [illegible] used for hanging curtains across the doorways, a much needed protection in the rainy season. In some cases another pair were found on the floor level, so that the hanging could be secured both at top and bottom from flapping in the wind. These hooks always had their points upward, so that loops could be easily placed over them. Nothing of this kind was found in Structure 1. The false arch, by which *all* Maya structures are roofed,* was standing to the height of the capstone in this building. This type of roofing is made by projecting the courses of two opposite walls slightly beyond the courses next below them in each case, and continuing this operation until the walls have been drawn close enough together to be bridged with a capstone. From this building it was thus possible to ascertain the approximate height of the rooms here at Quirigua, i. e., about nine or ten feet.

The quarries from which the building stone was obtained are some two and a half miles west of the city. The material in Structure 1 is a sandstone of rather fine grain, while that in Structure 2 is a volcanic rock, much harder and stronger. Both were worked with stone chisels, basalt being the commonest material. Several such chisels were found during the course of the excavations. They varied from 4 to 6 inches in length, had but one cutting edge, and were shaped to fit the hollow of the hand. There was no indication that they had ever been supplied with any form of handle.

In addition to the specimens collected, the most important results of the season's work were (1) the discovery of the new hieroglyphic texts and the exceedingly important data which they present, (2) the discovery that the upper half of the façade in Structure 2 was *sloping* rather than vertical, (3) the discovery that all sculptured stones were originally covered with a coating of white lime plaster varying from a very thin slip to one half inch in thickness, and (4) the discovery that Structure 2 was of greater antiquity than Structure 1.

* Throughout the length and breadth of the Maya area, from Yucatan in the north to Honduras in the south, and from the Isthmus of Tehuantepec in the west to British Honduras in the east, the writer knows of not a single authentic case of a Maya building having any other kind of a roof. John L. Stephens ("Incidents of Travel in Yucatan," Vol. II., pp. 281, 282) claims that he found a flat ceiling at Tuloom, on the east coast of Yucatan, but this statement has never been verified.

New System of Electrically-heated Hot Water Supply

A DISADVANTAGE of the electrical heating of hot water for general domestic supply is that when the temperature of the volume of water is lowered on drawing off a considerable percentage of the total amount by the incoming cold water, a long time is required to regain the normal temperature. To avoid this difficulty a form of electric heater has been devised in which part of the water only is heated directly by electrical energy, the remainder being heated indirectly by the first part. An inner cylinder contains the portion to be heated directly by an immersed resistance unit. The remainder of the water is contained in an outer jacket and receives heat from the inner cylinder through a wall. In order to allow the inner volume (from which the draw-off pipe runs) to become hot enough in a short time, the separating wall is designed to hinder the flow of heat to some extent. Thus the electric heating is applied to only one third of the total volume instead of to the whole, so that the temperature rises much more rapidly than by the ordinary arrangement.

A Polar Drift à la Nansen

ACCORDING to the *Zeitschrift der Gesellschaft für Erdkunde zu Berlin* a Spanish expedition under Señor Gisbert will embark this summer at a point near Point Barrow, Alaska, for a drift of several years in the North Polar Basin, after the example of Nansen's famous journey in the "Fram."

Notes and Queries.

Kindly keep your queries on separate sheets of paper when corresponding about such matters as patents, subscriptions, books, etc. This will greatly facilitate answering your questions, as in many cases they have to be referred to experts. The full name and address should be given on every sheet. No attention will be paid to unsigned queries. Full hints to correspondents are printed from time to time and will be mailed on request.

(12666) E. L. B. writes: *Re* item "An Ingenious Weather-cock," under Notes for Inventors, on page 589 of your valuable journal, I wish to advise that an indicating device similar to that referred to was described in *Amateur Work*, vol. 1 (June, 1902) pages 180 to 183, inclusive, four figures, under the caption "An Electric Wind-vane," by Paul M. Benedict. This device uses commutated currents in connection with "electro-magnets and compass" indicator. Also see "An Electric Wind Vane," by C. E. S., the *Model Engineer and Electrician* (London) vol. xix, No. 375, pages 11 to 13, inclusive, and No 376, pages 27 to 30, inclusive, seventeen figures. (July 2nd and 9th, 1908.) Indicator works on the principle of the annunciator. Being interested in meteorology, I have designed an electro-magnet indicator, utilizing a soft iron armature instead of a compass needle, the armature being kept in synchronism with the wind vane by means of a special commutator, which shifts the current from closed circuit batteries through the several magnets in proper sequence. I have also used a special rheostat operated by the wind vane and in circuit with an ammeter directly calibrated to show direction. I have no desire to discourage inventive research in this particular, but as the devices enumerated above cover the field pretty thoroughly and quite satisfactorily, there is not a great deal left for the "successful inventor" to invent. A We thank you for your interest in the matter of the electrically indicating wind vane Your observations are quite true There is no glory nor gold here for an inventor to obtain; but there is for the amateur who is possessed with the laudable desire to "make something" We have ourselves devised several arrangements of this sort in our own weather observations. There are always new men coming up who wish for such devices That is of course our reason for publishing such plans as we do in our Laboratory at Home and the Workshop section. It is not that they are absolutely new or wholly original, but that these devices will meet some one's eye who is just now in want of some such thing Any reader wishing to refer to the original description will find it in Vol. 106, No. 26, on page 589.

(12667) K. B. says: 1. What is the lightest known gas? How is it obtained? A. The lightest known gas is hydrogen The decomposition of water by electricity yields this gas It may be generated by the action of hydrochloric acid upon zinc, forming zinc chloride and liberating the hydrogen which the hydrochloric acid contains. When a piece of sodium is dropped into water, the gas which comes off is hydrogen This is too expensive for commercial purposes. The action of warm sodium hydroxide upon aluminium causes the evolution of hydrogen from the sodium hydroxide and the formation of aluminium hydroxide. The first method given is the cheapest and the one most generally employed for obtaining hydrogen. 2. What kind of gas passes off in the charging of an Edison storage battery? What is its relative weight to air? A. Hydrogen is evolved in the charging of the Edison storage battery from the decomposition of water Hydrogen is about 0.07 as heavy as air, more exactly, it is 0 0696 times as heavy as air 3 How much will a cubic foot of gas 25 per cent lighter than air lift? A. A cubic foot of air weighs 0.08 pound. A cubic foot of a gas which is 25 per cent lighter than air would weigh three-fourths as much as air, or 0 06 pound. In air it could, therefore, lift the difference between its weight and the weight of a cubic foot of air, or 0 02 pound.

(12668) W. F. says: If it were possible to take a compass over a line where there is no declination, and reach the North Pole, would the needle turn around? That is, would it continue to point to the north after passing over the pole? Such is the result when a compass is moved around a sufficiently strong magnet. A. If an ordinary compass needle, which is pivoted so as to swing in a horizontal plane, were carried along a line of no declination to the North Magnetic Pole, it would point to the true north until the Magnetic Pole was reached. When it was over the pole it would not have any directive power, that is, it would stand indifferently in any direction it happened to assume. If it were now carried forward toward the earth's geographical north pole, the needle would be reversed, and the north end of the needle would still point toward the magnetic pole it had just left. The needles of compasses point toward the magnetic and not toward the geographic poles of the earth. If a magnetic needle is hung so as to swing in a vertical plane, and carried toward the north, its north end will turn down as it proceeds until it arrives over the Magnetic North Pole, when it will stand in a vertical position, its north end being downward toward the earth. As it is carried on toward the earth's north geographical pole, the north end of the needle will be directed more and more toward the south, the pole it has left behind it.

NEW BOOKS, ETC.

THE OLD CLOCK BOOK. By N. Hudson Moore. New York: Frederick A. Stokes Company, 1911. 12mo; 339 pp.; 104 illustrations. Price, $2.40 net.

Those who have enjoyed and profited by "The Old China Book" and "The Old Furniture Book" will be pleased to hear of this very charming volume by the same author. English clocks are historically dealt with and described in the first of the two main divisions of the work, and American clocks and clockmakers are familiarly treated in the second division. The absence of available literature dealing with the earlier clockmaking activities of this country gives Mr. Moore's volume an added value, though the records are at best but sparse, and the products elusive. "Wag-on-the-wall" clocks were made in quantities in America up to 1830, but the author wrote forty-two letters in the effort to find an American clock of this style, without the least success. An illustration of one is given, but its standing as an American-made article seems doubtful. Speaking of illustrations, the plates accompanying the text will be a delight to all those of antiquarian tendencies. Every shape and size is here, in every degree of simplicity and ornamentation. The peculiarities indicating various makers are pointed out, and other means of identification are given. The care and repair of old-fashioned timepieces is condensed from the directions of Chauncey Jerome. A list of clockmakers, English, Continental, and American, concludes the volume.

MANNHEIM AND MULTIPLEX SLIDE RULES. By L. W. Rosenthal. New York: The Eugene Dietzgen Company, 1911. 16mo.; 67 pp. Price, 50 cents.

The slide rule is of such universal application, and is so simple to operate, once the principles are well understood, that it is extraordinary that the number of rules in use is comparatively few. The present volume tells how to use both the Mannheim and multiplex slide rules, both of which are excellent. Perhaps the most interesting chapter in the little book is that devoted to conversion ratios, dealing with geometrical ratios, ratios of length, ratios of area, ratios of capacities, ratios of weights, ratios of velocities, ratios of weights, lengths, etc., ratios of capacities and weights, ratios of pressures, ratios of work, and ratios of unit cost.

ELEMENTARY GRAPHIC STATICS. By W. J. Crawford, D.Sc. Philadelphia: J. B. Lippincott Company, 1911. 12mo.; 131 pp.; illustrated. Price, $1.

A short time ago we took occasion to mention favorably a textbook by Cathcart and Chaffee entitled "The Elements of Graphic Statics." This has been condensed and, with the matter mainly confined to the properties and general uses of the force and equilibrium-polygons, appears as "A Short Course in Graphic Statics." The "Elementary Graphic Statics" of W. J. Crawford presents another short course. Both are good, but while the first-named excels in plan and arrangement, and in some respects goes more deeply into its subject, the latter starts with simpler definitions, constructs simple apparatus, includes review questions, and will probably prove the more attractive to the absolute tyro.

CONCEALING-COLORATION IN THE ANIMAL KINGDOM. An Exposition of the Laws of Disguise through Color and Pattern. Being a Summary of Abbott H. Thayer's Discoveries. By Gerald H. Thayer. New York: The Macmillan Company. 4to.; 260 pp.; 16 colored plates and 57 black-and-white plates. Price, $7 net.

It is fitting that a book setting forth the observations and deductions of an artist should be a magnificent specimen of the typographer's art, and the publishers are indeed to be congratulated upon the result. The author defines concealing-coloration as simply that which enables the wearer to be mistaken for certain details of the scene, and his discovery—or theory, if you prefer it—is that almost every living creature reproduces in marking and tinting the background of his natural habitat. No matter how conspicuous an object he may be when removed from his own domain, while there his costuming is that best fitted to melt into its surroundings and endow its wearer with a gift approaching that of invisibility. The supreme feature of the volume is its remarkable illustration, in which birds, beasts, fishes, reptiles, and insects are shown with scientific and artistic accuracy beneath the light, and with the background, of their native haunts, where the concealing function of their markings has free play. We understand the volume was eight years in preparation. It certainly represents a vast amount of sympathetic and intelligently ordered labor, and offers much material for thought and for further trained investigation.

ELIZABETHAN INTERIORS. By C. J. Charles. London: George Newnes, Ltd. New York: F. Greenfield, 1911. Folio. 40 pp. Numerous plates.

This superb work is printed from original plates, etchings, and drawings, and the selection of them is most admirable and the plates beautifully reproduced. It is, in fact, a book which will be welcome to the libraries of all architects and connoisseurs. The text, which is beautifully set in very large type, is printed on handmade paper, the impression being sunk into it to match the plate marks of the plates themselves. It is attractively bound in morocco and boards. The purity of the Elizabethan style and its adaptability to more pretentious homes is well brought out. The examples shown include many interiors in this country. The first edition consists of 900 copies. It is one of the most attractive architectural books

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are sharp, the articles short, and the facts authentic, the contributions will receive special attention. Accepted articles will be paid for at regular space rates.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement

Board of Trade Report on the "Titanic"

TO the readers of the SCIENTIFIC AMERICAN the most interesting portion of Lord Mersey's report on the loss of the "Titanic" will be those sections in which he makes recommendations as to the elements of safety which should be incorporated in the construction of future passenger steamers. From the very first this journal has held that the most serious feature of the loss of this vessel was the fact that she went to the bottom so soon after the collision, and we have shown that her failure to remain afloat until the rescuing vessels could reach her was due to the omission from the ship of certain protective features in the way of more complete sub-division which, had they been present, would probably have prevented the loss of a single life.

Lord Mersey attributes the loss of this ship primarily to high speed and an insufficient lookout. He would have been closer to the facts if he had stated that the collision was due to these causes and the loss of the ship to her insufficient sub-division below the water line. By implication if not by direct arraignment the report must be taken as a scathing indictment of the provisions of the Board of Trade, and the public may rest assured that these recommendations, following along very much the same lines as those to be found in the report of the Senate's Investigating Committee, will lead to some very thoroughgoing reforms in the Board of Trade. It is naturally gratifying to the SCIENTIFIC AMERICAN to note that the recommendations of a structural character made by Lord Mersey are identical in character and number with those which were suggested by this journal in its first analysis of this disaster made within a few days of its occurrence.

It is recommended that the Board investigate the practicability of providing sea-going ships, in addition to their watertight transverse bulkheads, with a double skin carried above the water line, or with a longitudinal vertical watertight bulkhead on each side of the vessel, or with both. The Board is instructed to investigate the question of providing a watertight deck or decks, stretching along the whole or part of the length of the ship at a convenient distance above the water line, and it is to determine whether the openings should be watertight doors or some other device.

It is further recommended that the subdivision of the vessel should be so adjusted as to keep the ship afloat with the greatest proportion of her length in communication with the sea. This of course refers to the present provision, which contemplates only two adjoining compartments being open to the sea. This provision should certainly cover three or even four compartments.

A most important recommendation is that the Board of Trade be empowered to enforce their conclusions on the foregoing points, and to require that the designs of ships should be submitted to it in the early stages of their construction.

We have frequently pointed out that ships which embodied these constructive features would be practically unsinkable—that at least they would remain afloat long enough for rescuing vessels to transfer the passengers. To this extent they would serve as their own lifeboats. Nevertheless, in view of the fact that the majority of ships are not built along the lines suggested in this report, we are glad to note that Lord Mersey recommends that the lifeboat accommodations on sea-going vessels be based on the number of persons carried instead of on the tonnage of the ship, and that they be sufficient for all on board.

Important also is the recommendation that an international conference be called to agree on a common rule for the sub-division of ships, also as to life-saving apparatus, wireless regulations, speed in the ice regions and the use of searchlights.

A Bureau of Farm Power

THAT highly efficient department of the Federal Government which is devoted particularly to the interests of the farmer, contains among its subdivisions a bureau for the investigation of soils, a bureau of chemistry for the analysis of fertilizer, a bureau of plant industry to study the bacteriological problems connected with plant production and plant nutrition, a bureau of entomology to obtain and determinate information regarding injurious insects affecting field crops, fruits, etc., a bureau of biological survey which recommends measures for the preservation of beneficial and the destruction of injurious species of birds and mammals, a bureau of animal industry for the inspection of animals, meats and meat food products, and the investigation of dangerous diseases among live stock, and a weather bureau which will keep the farmer informed as to meteorological conditions. It would seem that with all these different bureaus the interests of the farmer were well taken care of. However, there is one important branch of farming that has been entirely ignored by the Department of Agriculture, namely the subject of farm power. The American farmer has outgrown the age of hand labor and even animal labor is now on the wane. Steam power was introduced on the farm many years ago and of late the internal combustion engine has been playing a very important part and now electricity is beginning to be used.

The epoch of mechanical power on the farm has already begun, and it is important that farmers be educated upon matter pertaining to labor-saving machinery. Realizing this need, Mr. H. T. Rainey of New York city introduced a bill in the House of Representatives last month to establish in the Department of Agriculture a Bureau of Farm Power. The province and duties of the bureau are "to investigate and report upon all matters pertaining to methods of furnishing power on farms and all labor-saving machinery adapted for use on farms and the use of electricity, gasoline and steam in propelling farm vehicles in operating plows, reapers, mowing machines, threshing machines and other machines and implements used in planting, cultivating, harvesting and marketing corn, wheat, oats, potatoes, hay, rice, vegetables and all other agricultural products.

"It shall be within the province of said bureau to make diligent investigations into the matter of machines and labor-saving devices used in the dairying industry as conducted on farms and into the methods of heating and lighting all farm buildings. In general, said bureau is authorized and directed to investigate diligently all machinery and devices which will lessen the amount of labor necessary in agricultural pursuits and lessen the expense of producing and marketing such of the necessaries of life as are produced on farms and to report the results of said investigations to said Department of Agriculture."

We hope that Congress will see fit to establish this much needed bureau.

A Question of International Good Faith

"ARTICLE 3. The United States adopts as the basis of the neutralization of such ship canal the following rules, substantially as embodied in the Convention of Constantinople signed the 28th of October 1888 for the free navigation of the Suez Canal, that is to say: 1. The canal shall be free and open to the vessels of commerce and of war of all nations observing these rules, on terms of entire equality, so that there shall be no discrimination against any such nation, or its citizens or subjects, in respect of the conditions or charges of traffic or otherwise."

The above quotation is from a treaty concluded in 1901 between the United States and Great Britain, known as the "Hay-Pauncefote Treaty," in which, in consideration of certain concessions made by Great Britain the United States agreed, among other things, to operate the canal under similar conditions as regards the ships of all nations making use of the canal.

There is now before Congress a bill which proposes to remit the tolls on ships flying the flag of this country.

It does not take a legally-trained mind to see that such exemption would be a distinct breach of faith on the part of our Government. The question is one of simple, every-day morality. Questions of moral right are universal in their application, and the code of honor is as strict in its [illegible] Government like our own as [illegible] citizen. Is it not indeed [illegible] breach of faith on the part [illegible] himself only, whereas a breach [illegible] the United States Government [illegible] of the ninety-five millions of people who live under its flag?

The peril of the present [illegible] good faith lies in the fact that the [illegible] clouded by sophistry. Specious catchwords and misleading phraseology may easily divert the [illegible] a busy people from the real points at issue in a controversy of this kind. "We built the canal; why should we not make the other people pay for it?" "The United States has invested nearly $400,000,000 in this enterprise, and why should we be called upon to play the part of the philanthropic benefactor, by charging our own ships the same rate of toll as we charge the ships of other nations, who have contributed not a single dollar to the great work?" The answer to all this is, that our Government, after a careful review of the whole situation, and in view of the collateral advantages to be secured in the way of the abrogation of previously existing treaties affecting the Isthmus, and the pledge of Great Britain that the Canadian and the Suez Canals shall be operated on terms of equality, did enter into a solemn agreement to operate the Panama Canal upon terms of equality; and if the United States Government should now violate that treaty by operating the canal upon terms of inequality, it will stand condemned in the eyes of the whole world as having committed an act of international dishonor.

Furthermore, the exemption of United States ships from the payment of tolls would be to divert a portion of the reasonable profits of the canal into the pockets of certain private corporations. We cannot shut our eyes to this fact. The remission of these tolls will not mean the return of any profits of operation back to the National Treasury, and no amount of argument can possibly show that it will. It is urged, of course, that the remission of tolls will serve as a powerful stimulus to the upbuilding of our merchant marine. But we are not by any means prepared to admit that it would. What we do claim, however, is that whatever collateral benefits might be secured, it is impossible to overlook the fact that the gain would be made at the cost of our national reputation for honor and square dealing.

The SCIENTIFIC AMERICAN, as our readers well know, is an earnest advocate of the upbuilding of our shipping industry, but upon mature consideration we feel that this expedient of remitting Panama tolls is not, and in the nature of things, never can be, the legitimate way to achieve this object.

The construction of the Panama Canal must rank as the greatest achievement of a physical character that has ever been undertaken and successfully put through by the United States. We have gained an enviable reputation thereby, and in this particular field our prestige as a great engineering people has been immeasurably increased. It would be a lamentable commencement of the operation of the canal if we were to cloud this great project by following a course which would bring down the condemnation of the whole civilized world.

"Making" Rain in Battle Creek

ON July 23d Battle Creek, Mich., "put itself on the map" (to quote a local paper) by holding an exhibition of the alleged efficacy of dynamite in producing rain. If the purpose of the exhibition was to attract a large and lucrative influx of visitors for the benefit of the community in general, or to advertise the wares of a local manufacturer who financed the enterprise, or, finally, to promote the sale of explosives, then the citizens of the Michigan town are to be congratulated upon the results of their efforts. Mention should also be made of the moving-picture men, who were present in force to make the most of an unusual event. About 4,500 pounds of dynamite were exploded in the course of the afternoon. A rain area of a hundred thousand square miles, more or less, which had been drifting eastward from the Dakotas since the previous morning reached Battle Creek the day of the explosions; in fact it was drizzling at that place some hours before the firing began, and heavy showers fell all over southern Michigan in the course of the day. In spite of these facts, the rain-makers claim that the particular fraction of the general rain storm that occurred in their vicinity was the result of the explosions. It is entirely superfluous to comment upon this claim, beyond saying that the rain-making hallucination is, apparently, one of the incurable forms of mental disease. Of course any one with a slight knowledge of meteorology, and the current weather map at his disposal, could have "made" rain at Battle Creek on the day in question in the same way in which the [illegible] in a savage country, having a convenient almanac at hand, "makes" an eclipse of the sun or the moon in order to impress the natives.

Engineering

Quantity of Canal to be Dug.—On July 1st, the grand total of canal excavation was 173,269,815 cubic yards, leaving to be excavated 22,063,564 cubic yards. This means that more than one-eighth of the entire amount necessary for the completed canal remains to be excavated.

Electric Power from Gatun Lake.—Electric power will be used almost exclusively for operating the Panama canal. The hydro-electric station will be situated adjacent to the north wall of Gatun spillway and the installation will have a capacity of 6,000 kilowatts. The average hydraulic head throughout the year will be about 75 feet. The maximum quantity of water diverted for hydro-electric development will be approximately 7 per cent of the minimum water supply, and will be the excess which is not required for lockages, evaporation, and leakage.

Cuniberti Favors Life Pontoons.—The pontoon method of saving life in the event of the foundering of a ship, as illustrated recently in the SCIENTIFIC AMERICAN, finds an illustrious advocate in Cuniberti, the chief naval architect of the Italian navy. He believes that the upper aft portion of a ship, containing the cabins, etc., should be constructed of wood and form a structure independent of the rest of the ship. This should be bolted to the hull by fastenings which could be readily unlocked in the event of the loss of the ship. Fred T. Jane, who mentions the fact in the *Navy*, suggests that the idea is not any more far-fetched than the idea of building dreadnoughts when it was first suggested by Cuniberti.

Lexington Avenue Subway, New York.—The largest work of subway construction now being carried on in the world is that being done below Lexington Avenue in this city. The line, which will be four-track throughout its entire length, is about 10 miles long. Eight of the 10 miles are now under active construction, and the total cost of the work on this 8 miles alone will be over $35,000,000. Over 3,000 men are engaged on this section. Work is also being prosecuted on the four-mile, four-track subway on Fourth Avenue, Brooklyn, and the Center Street loop subway is being completed. Altogether on the three systems there is now under contract about $81,000,000 worth of work, covering 13½ miles of four-track roads.

A Forty-knot Hydroplane.—England is again about to make an effort to recapture the Harmsworth cup for motor boats, which is now held in America. Four boats have been built, and of these the fastest is the "Maple Leaf IV," a 40-foot boat, with engines of about 600 horse-power. In a contest recently held, the "Maple Leaf," over a 33-knot course, maintained the remarkable speed of over 40.03 knots or about 46 miles an hour. Considering the length of the course this is certainly an extraordinary speed; and in view of the fact that several boats have been built in this country which are credited with equally high speed (that is to say, if the newspaper reports are correct), we may look for an excellent contest this summer on Long Island Sound.

Reduce Railway Speed.—The Public Service Commission found that the breaking of the rail which caused the wreck of the Twentieth Century Limited was largely due to the high speed of the train, and it referred to the schedules as being "too fast for safety." On the other hand, we notice that recently the engineers of the Union Pacific Railroad stated that the breaking of rails could be prevented by putting more metal into the base. Both points of view are correct; but we are inclined to agree with the Public Service Commission that, as matters now stand, and in view of the heavy wheel loads, the rail is not equal to its task. If rails were heavy, and if the specifications were stricter and the process of manufacture were carried out with greater care, railroads could run their trains as fast and even faster than they do to-day, with impunity. It is quite possible to manufacture rails which will stand up under any traffic whatsoever; but it is certain that the average rail used to-day on American railroads is not equal to its duties.

Double-deck Cars for New York.—It is reported that the Interborough Company is studying the question of the introduction of double-deck cars in New York city. This is the right idea; indeed, the SCIENTIFIC AMERICAN, many years ago, had a series of articles strongly advocating the use of this type. The introduction of an upper deck practically doubles the capacity of the car, without involving any proportionate increase in the weight or in the power necessary to drive it. The number of passengers per unit of length is doubled, and when the public get accustomed to this type, we believe that there will be very little increased delay at the stopping places, due to the larger number of people boarding or leaving the cars. The low car which is running experimentally in New York would be well adapted for double decking, as the total height of such a car with another deck would not be so great as to interfere with the overhead structures, at least on many of the crossings in the city.

Science

Mt. McKinley.—A telegram has been received from Mrs. George Brown, mother of Belmore Brown, the companion of Prof. Herschell Parker on his third attempt to ascend Mt. McKinley. The telegram states that a height of twenty thousand feet was reached, which means that the summit is still unconquered.

Plans of Capt. Amundsen.—The discoverer of the South Pole expects to return to Europe in September and will make a series of addresses before the principal geographical societies, beginning with the Norwegian Geographical Society in Christiania. He is to address the Royal Geographical Society in London on November 18th. The Norwegian Storthing (parliament) has voted him a grant of 136,365 kroner (about $36,818) toward his prospective north polar expedition.

The Cost of Discovering America.—The English newspapers print a report from Madrid to the effect that some ledgers discovered at Palos, Spain, contain interesting information on the cost of discovering America by Columbus. The sum total for which America was discovered amounted to $7,000, or 38,000 pesetas. This was distributed as follows: 14,000 pesetas for armament; 2,000 pesetas for personal expenses of Columbus and his officers and crew; 22,000 for general expenses during the eight months for which the voyage lasted. The sum of $7,000 in 1492 represented $70,000 in 1912.

Mikkelsen Heard From.—A most amazing tale of hardship endured in the polar regions is that of Capt. Mikkelsen published in the New York *Times*. He suffered from the very beginning. Abysses, storms, lack of food, scurvy, all imaginable obstacles to polar exploration he encountered. Only the briefest details have been received outside of the news of the safe return of the men. Capt. Mikkelsen and his companions reached Denmark Firth on May 20th, 1910. There they found the records left by Erichsen. They began their return journey nine days later and encountered terrible hardships. They reached Shannon Island. They had abandoned all hope of their rescue when they were picked up by a Norwegian fishing vessel on July 17th last and brought back to Aalsund.

The Alaskan Reindeer Herds.—During the ten years, 1892-1902, the U. S. Bureau of Education introduced 1,280 European reindeer into Alaska, where the natives were threatened with starvation owing to the destruction of the once abundant American reindeer, or caribou. It was also expected that these animals would serve the many useful purposes in the domestic economy of the Alaskans for which they have been so highly prized in northern Europe and Asia. The success of the undertaking has been remarkable. A recent official report on the subject states that these herds, which are under the care of the teachers at the government schools, now number 33,629 head, and they are increasing rapidly. Their meat is in great demand by both whites and natives, and their skins supply the best winter clothing. It is expected that the exportation of reindeer meat will soon become an important industry. Above all, the reindeer has proved a most efficient civilizing agency. The success of the Alaskan reindeer enterprise induced Dr. Wilfred Grenfell, in 1908, to import 300 reindeer from Lapland into Labrador, where they have now increased to about 1,200, and are a great boon to the natives. Last year the Canadian government bought 50 of Dr. Grenfell's herd for introduction into northern Canada.

Observation of Solar and Lunar Halos in France.—The most complete descriptive account of all known forms of solar and lunar halos is that published last year by Louis Besson in *L'Astronomie*, the organ of the Astronomical Society of France. The principal purpose of M. Besson's memoir was to call attention to the urgent need of accurate and systematic observations of these interesting phenomena, many of which have so rarely been seen and described by trained observers that the data needed for their theoretical discussion are decidedly fragmentary at present. This suggestion has met with a hearty response on the part of French meteorologists and astronomers, and every number of *L'Astronomie* now contains reports and descriptions of halos; often accompanied by drawings, and sometimes by photographs. Several rare forms have already been reported. In only one other country, viz., Holland, is there a large and active corps of halo observers. Their observations have been published annually by the Meteorological Institute of the Netherlands and have greatly enriched the branch of science dealing with this generally neglected subject. The history of halo-observing the world over has been remarkable in the fact that in the days of our grandfathers these phenomena were much more generally watched for and more widely known to scientific men than they are to-day. A revival in the study of halos is an urgent desideratum, especially in English-speaking countries. As halos are especially common in the polar regions it is desirable that polar explorers should acquaint themselves with the detailed literature of the subject (all of which is in French and German) before they embark upon their travels.

Aeronautics

The Military Breguet Biplane.—The new military biplane designed by Breguet is a remarkable machine in every way. The power plant is mounted in front as in most monoplanes. A 14-cylinder 100 horse-power Gnome engine drives two two-bladed propellers through reducing gear. Only four very stout vertical struts are employed between the planes. The body is of torpedo shape and is constructed of steel tubing, steel girders and ash. Wood plays but very little part in the construction of the machine. The machine can be completely folded in five minutes.

The National Balloon Contest.—On July 28th seven balloons rose from Kansas City, Mo., in the National Elimination Race. The winner was the balloon "Uncle Sam," piloted by Capt. H. D. Honeywell, Roy F. Donaldson, aid, entered by the Kansas City Aero Club. The distance covered was about 925 miles, the balloon landing on the historic battle ground of Bull Run. The second in the race was the "Kansas City II," piloted by John Watts, George Quisenberry, aid, entered by the Indianapolis Aero Club. The distance covered was about 640 miles. The third in the race was the balloon "Drifter," piloted by Albert Holtz, Charles Trautman, aid, entered by the Cincinnati Aero Club. The distance covered was about 425 miles.

Requirements for Naval Aeroplanes.—On the 25th ult. specifications for hydro-aeroplanes, with which, by another year, it is hoped to have every battleship equipped, were issued. Constructors are requested to inform the Navy Department by August 15th if they intend building machines to fulfill the requirements, and to state when such machines will be ready. They are required to carry, as a full load, two persons of a combined weight of 350 pounds, together with a wireless outfit and other instruments and supplies for a 4-hour flight. A maximum speed of 55 miles per hour must be shown as an average of ten flights—five with the wind and five against it—over a mile course, and 50 miles per hour throughout the 4-hour endurance test with full load. The latter test will be made over a 5-mile triangular course, the speed being determined by a recording anemometer. All machines must rise from the water in still air, with a run of not over 1,000 feet; must climb to 1,500 feet in one or more big spirals and in a given time (not yet determined) must turn without skidding, stalling or sliding, in a circle of 200 yards radius, and must glide from a height of 500 feet with power off a distance of 2,500 feet in a horizontal direction. Air-cooled motors are preferred and an extra premium will probably be offered for a heavy-oil motor or one using kerosene or alcohol. It must be arranged to be started from the seat by the pilot. The machines must be able to be hoisted on board ship intact and to be quickly disassembled. The hydroplane floats must have watertight compartments and means of draining readily. The aeroplane must be able to remain upright on the surface of the sea in a 20-mile wind when the motor is stopped.

A Woman's Opinion of Aviation.—Mrs. Elizabeth Hiatt Gregory, a woman writer who specializes on aeronautics, gave a lecture before the Aeronautical Society of New York on "Woman's Part in Aviation." It was the opinion of Mrs. Gregory that flying is an unsuitable occupation for women, and under no circumstances should she be allowed to use an aeroplane, since its safety is mostly a matter of gamble. Instead of relying upon an instrument, the aviator trusts principally to his own watchfulness, which obviously leaves the margin of danger very great, as there are many accidents due to uncontrollable error on the part of the machine or tricks of the wind. Mrs. Gregory stated that aviators put too much stress on their ability to ward off accidents by this watchfulness. As an example she referred to the late Miss Harriet Quimby, whose very first accident resulted in her death. "A few days before her death," said Mrs. Gregory, "Miss Quimby told me that driving an aeroplane was as safe as riding in an automobile, as long as one was careful. She had tried both. She thought mishaps with few exceptions came to those who attempted foolhardy feats. She claimed that in driving an automobile the driver has sudden starts and stops, twists and turns through the crowded thoroughfares; while the air-pilot must constantly be on the lookout for cross-currents and pockets that may upset his craft." Miss Quimby thought women were as well fitted for handling an aeroplane as men. It was merely a matter of personality, she maintained. The lecture was illustrated with lantern slides, showing both the American and foreign women of the air. Pictures of men fliers in spectacular feats were also thrown on the screen. Mrs. Gregory said that while only twelve women in the world have been granted pilots' licenses, there have been five deaths. Three of these have been American women. The first was Miss Denise Moore, an American girl, who while completing her tests for a license at the Farman School in Paris, had her fatal fall. The other two were Miss Harriet Quimby and Mrs. Julia Clark. Both Miss Quimby and Mrs. Clark had made their qualifying tests.

The Cream Separator

Its Development, Advantages and Unsolved Problems

The parts of a revolving bowl fastening nut, shell, liner and feed tube

FIFTEEN years ago the creameries of this country still followed the custom of maintaining cream routes, from which the hand-skimmed cream was collected from three to six times a week. A few years later these routes were a thing of the past. Instead, separator stations were maintained at centrally located points, to which the farmer could bring his milk, have it separated in a few minutes, and return with his skim milk and receipt for his cream. But now another change has come over the industry, and instead of taking his milk to one of the numerous separator stations, each farmer separates his milk on his own farm and in his own separator, and once or twice a week, when he goes to town to deliver eggs and to buy provisions, he takes along the cream. The one great factor in these revolutionary changes in a great industry is the centrifugal separator, and it is the purpose here to trace very briefly the growth and development of the separator, to point out its advantages, and to discuss some of the problems still unsolved.

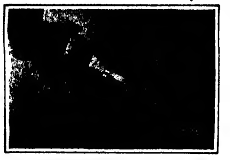
Your milk, homogeneous when bottled at the dairy, will be found in two fairly well defined layers when you bring it in from the doorstep early in the morning. A few hours later, the line of separation will be found at a lower level. The separation is due not to one cause, but to several, but the most important single cause, and the one which determines the relative positions of the layers, is the fact that the particles of the lower watery layer are heavier, or rather have greater mass, than the particles of the upper or oily layer. The older methods of separation all depended on the force of gravity acting to separate the two component parts of the milk, and all improvements were directed to modifying other conditions. It is a well known fact that the relative viscosity of the two constituents influences the rapidity of separation, and the relative viscosity can readily be modified through certain changes in temperature. Both the shallow pan method and the deep can method depended for their efficiency on a favorable adjustment of viscosities. The water dilution method was only another step in the same direction, but although all of these methods were in use for many centuries, no appreciable advance was made in the industry.

The mass of a body cannot be changed. Its weight, or apparent mass, can however be changed by putting the body in motion. A very simple experiment will prove this. If a rapidly descending elevator comes to an abrupt stop, the sensations of the passenger will be convincing. A small weight on a spring balance suspended in the elevator would give the exact measure of this apparent increase in mass. The spring balance may also be used in another way to demonstrate the same truth. Secure a weight to the balance, and swing it at arm's length as you would a sling. While in motion, the pointer indicates a greater mass than when at rest. The mass remains the same, but apparently it increases, and in this case, the force which produces this result is known as centrifugal force. This force is similar in effect to that of the force of gravity, but within wide limits it can be increased at will.

A liquid composed of two liquids of different densities, as an emulsion of oil and water, remains stable only by virtue of the attraction of the particles for one another, which varies with the different liquids. In the case of oil and water, this attraction is very small, and to break up such an emulsion it is necessary only to apply a force which will overcome the attraction between the particles of oil and the particles of water. Gravity alone will do it by acting more powerfully on the water than on the oil. If the force of gravity would be multiplied say by ten, then the weights would be multiplied by ten and the difference between the weights would be correspondingly increased. This would mean that while the force which tends to hold the particles together remains the same, the force which tends to pull them apart is increased ten fold. The result would be a more rapid and a more thorough separation. The force of gravity, however, cannot be increased, but in the centrifugal machine we have a force which will accomplish the same result.

Throughout its development, the history of the cream separator is inextricably bound up with progress in a number of other arts. The high speeds necessary for efficiency were made possible only by many improvements in journal boxes and frictionless bearings. Then, too, the development of the separator had to wait on the development of steel—an extremely hard steel for the bearings and an extremely tough steel for the bowl. It must be remembered that the pressure generated within that thin wall of steel is as great if not greater than the pressure in a locomotive boiler. But we shall confine ourselves here to the development of the centrifugal machine for separating out the cream from milk.

Tool for holding together the disks of a liner while washing them. By the use of the tool the disks may be washed as a single piece.



Method of transferring the disks of the skimming device upon the tool preparatory to washing or of replacing the disks on the liner.

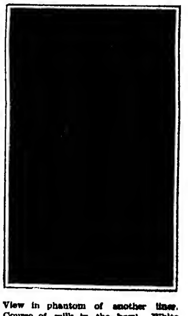
The first application was made about 1860, in Germany, with a glass tube swung rapidly about a center, to determine the richness of milk samples. The modern Babcock tester is identical in principle. It consists of a vertical spindle with radial horizontal arms on which graduated glass tubes containing milk samples are suspended. By rotating the spindle through its gearing, the tubes assume a horizontal position. The first attempts at separating cream from milk in larger quantities were made with a similar apparatus, pails being used instead of glass tubes. Then followed the single closed pail, centered in an upright position on a vertical spindle. The rapid rotation caused the milk to assume the form of a wall at the periphery of the pail, and when the machine was stopped, the two layers which had been vertical became horizontal, with the cream on top. All of these devices necessitated hand skimming after separation of the milk into layers. Such was the state of the art after twenty years of development, when in 1880 Houston and Thompson obtained a patent on a self-skimming separator which was continuous in operation. This machine was faulty in practice, but it marked an epoch in cream separator history because it pointed the way to other inventors, who quickly solved the mechanical problems involved in the working out of a successful separator of this type.

Sectional view, showing course of the milk entering a bowl and the paths of the skim milk and cream during and after separation.

The next great step was the invention of the liner, patented by Baron von Bechtolsheim in 1890. This consists of a number of division contrivances in the bowl, dividing the milk into thin layers, and intersecting the radial path of the milk in its passage toward the periphery. Separators up to that time had all been of the hollow bowl type. In nearly all, the milk was fed in through a central tube to the bottom of the bowl and the skimming was done at or near the top. The milk thus was caused to flow outwardly from the center and upwardly along the wall. The liner, however, broke up the milk into thin layers while under the influence of centrifugal force, and thus avoided the eddy currents which would tend to form in a hollow bowl. Before von Bechtolsheim's invention various division contrivances were already in use, but none of these were based on the liner principle. Baffle plates were well known. Their function was merely to compel the body of milk to partake of the motion of the bowl, since its inertia would otherwise cause it to travel at a slower speed. Thin horizontal plates, to obstruct the milk in its upward path, had also been in use. Dr. Gustaf de Laval,

(Continued on page 124.)

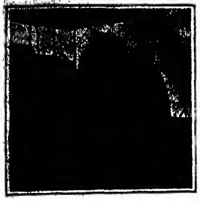
View in phantom of a de Laval disk liner structure in position on the spindle. The whole milk is fed through the hollow spindle *T* and emerges between the disks, through the openings in the wings *W*.



View in phantom of another liner. Course of milk in the bowl. White pointed arrows indicate whole milk, all white arrows show cream; black pointed arrows partially separated milk.

A general view of a separator with part of the machine shown in section in order to reveal the very simple gearing, the system of lubricating and the inner construction of the center balanced wheel.

A view showing a complete hand separator having a capacity of four hundred and twenty-five pounds of milk per hour. The machine measures forty-six and a half inches in height to the top of the can.



The International Motor Contest at Winnipeg

An Annual Traction Engine Contest that Means Much to Farmers and Manufacturers

By L. W. Ellis

THE great annual Motor Contest at Winnipeg is over and the addition of four great tables of definite information to that already brought out on the farm tractor, is a notable event in the technical world. Competition this year was keener, if anything, than ever before, and although some of the contestants in earlier meetings dropped out, the newer ones who took their places showed that they were rapidly overtaking the former leaders in efficiency.

The Winnipeg Motor Contest can hardly be said to have that diversity of interest that marks the contests in France, because under the conditions named there is little encouragement for the appearance of such a variety of types as were seen at Chelles last March. The American farm tractor has become practically standard in so far as the method of attaching the plows or cultivating instruments is concerned. The direct traction method prevails, and all of the tractors seen in the contest at Winnipeg were those having separate plows attached by chains to a drawbar at the rear of the engine.

This does not mean that the Winnipeg Competition has not brought out new types of machinery. Indeed, it is the one big event of the year, where the fond inventor or builder proudly brings forth his creation to find out how it compares with those of established reputation. Sometimes the new comers give a remarkably good account of themselves, and frequently all "dope" is upset by truly remarkable performances of some new machine. Last year the four-cylinder Aultman-Taylor gasoline tractor, which many, even of the technical visitors, saw for the first time at the Contest, gave the gold medal winner a close run, and this year two tractors of the same general type won, respectively, a gold medal in the class for larger gasoline engines, and a silver medal in the class for larger kerosene engines. The J. I. Case Threshing Machine Company appeared on the market this year for the first time with a gasoline tractor in addition to their regular steam engine line and with the smaller type won a gold medal in competition with several makes which have been represented in previous competitions.

The Holt-Caterpillar, a machine very similar in appearance to the Lefebre tractor pictured in the SCIENTIFIC AMERICAN SUPPLEMENT, June 29th, made a notable record in plowing after a less fortunate brake test. It demonstrated the efficiency of the peculiar type of traction wheel and would have received a silver medal in the larger gasoline class but for a penalty of 29 points for failure to be ready on the brake test—a failure due to the shortcoming of an expert who was intrusted with the preliminary work of getting ready for the Contest.

A four-wheel-drive tractor, made by Heer Engine Company, demonstrated great tractive efficiency in various ways, but unfortunately met with an accident to one of its drive chains while assisting a competitor out of a mud hole in the prairie, and was somewhat handicapped in the Contest. The American Gas Tractor was also a new comer and showed up very nicely as to construction and power, although scored quite low for a high fuel consumption, which should disappear with further refinement.

Among the older competitors the J. I. Case Company had things practically its own way in the steam engine classes, having the only engine in each of the two smaller classes and a comparatively easy victory over the Sawyer-Massey Company in the class for the largest engines. The latter company was unfortunate enough to meet with a minor accident shortly after the start in the plowing test, and it was necessary to draw fires until a new blow-off cock could be put in place. The Case Company was awarded the gold medal and two diplomas.

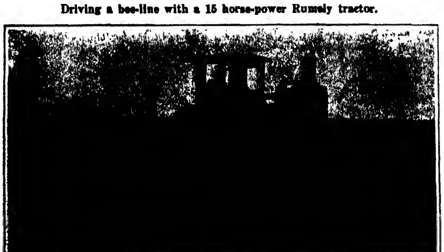
Driving a bee-line with a 15 horse-power Rumely tractor.



The J. I. Case gold medal winner in class B. Drawing five plows.

None of the other large steam engine concerns such as Reeves, Avery, Rumely, Nichols & Shepard, or The Russell & Co., entered the steam engine classes, although competing strongly in the market. There is a tendency to belittle the steam engine trade of the present because of the overshadowing number of internal-combustion tractors brought forth in these competitions. However, steam tractor firms are all apparently building as many engines as before, and some have greatly increased their business, even in the face of the strong gas tractor competition of the last few years.

The International Harvester Company, the Avery Company and M. Rumely Company have been consistent performers in these competitions for a number of years. This year the International engines won a gold medal in the smaller kerosene class and a silver medal in the smaller kerosene class; a silver medal in the larger gasoline class, and a bronze medal in the larger kerosene class, having had five entries in competition. The tractor, made by M. Rumely Company, won easily in the larger kerosene class and scored the highest number of points given to any tractor in the entire contest. The smaller Rumely tractor, with a motor somewhat different in design from the standard type, secured a silver medal in its class, though scored low on fuel consumption. The Avery Company secured two bronze medals, one on kerosene and one on gasoline, using the same type of engine in both cases.

Canada was not well represented in the contest although Goold, Shapley & Muir, of Brantford, won the silver medal in the smaller gasoline engine class, and Sawyer-Massey received a silver medal in the steam engine class. The greatest competition came in the class for the larger sizes of gasoline engines, and the number of large engines in the contest indicates that there is no likelihood of their being discontinued at an early date in favor of smaller tractors.

The entire motor competition was carried out in practically the manner described in the SCIENTIFIC AMERICAN, June 29th. The exhibition officials had provided this year a new testing shed, with two new friction brakes securely anchored to beds of concrete. With this and other new equipment, the brake tests were run off without delay. The two-hour economy tests showed a vast improvement in the fuel efficiency of the leading engines. Little criticism can be made regarding the handling of the economy brake tests, as all apparatus were so arranged that spectators could keep close check on all readings as to fuel and load, and there was little possibility of error

A half-hour maximum test was given each engine, the idea being to ascertain the highest amount of power that could be turned out continuously without causing the engine to show distress. Points were given on the steadiness of running, the condition of the engine, and for the excess of horse-power developed in the maximum test over what was developed in the

(Continued on page 124)

A Plan for Converting the Sahara Desert Into a Sea

What Would Happen if the French Flooded the Great Desert

By G. A. Thompson

A SENSATION was recently caused in Paris by the daring proposal of Prof. Etchegoyen, a distinguished scientist, who declares that France ought to lose no time in converting the vast desert of Sahara into an inland sea. He claims that, since "about a quarter of the whole desert area lies below sea level, the construction of a canal some fifty miles long through the higher land of the north African coast would immediately create a Sahara Sea equal in size to about half the extent of the Mediterranean." This canal, he states, would present no great mechanical difficulties because the coast land is composed of sand and soft rock formations.

The consequences of such engineering, he declares, would be gigantic. All the arid regions now surrounding the desert and those parts of the Sahara which are above the level of the ocean would be rendered as fertile as Europe, since the present sterile condition is due to no fault of the soil but is caused solely by lack of water. Millions of human beings could then support themselves in comfort, who now lead a miserable existence on the verge of starvation. Moreover, a great new colony could be added to the possessions of France, of which the political and economic importance can hardly be overestimated. A fleet of steamers would navigate the Sea of Sahara, the depth of which would vary from ten to sixty fathoms, and produce a flourishing traffic between Algeria and French West Africa. And the most remarkable result of all would be the alteration of the climate of all northern Africa from equatorial extremes of heat to the pleasing temperature of Natal, thus enhancing its value as a place of colonization for Europeans.

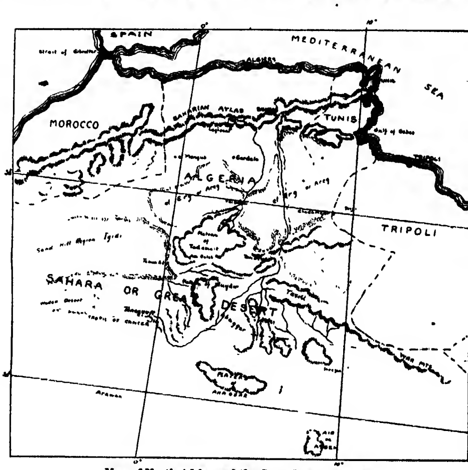
Prof. Etchegoyen's scheme is provoking much comment, and objections are not wanting. Certain meteorological experts cry out in horror that any tampering with weather conditions in Africa would transform the climate of Europe; that, if tropical Africa should become temperate, Europe would become arctic, and an alarming picture is drawn of England, Belgium, and Denmark lying under several feet of perpetual snow, and their inhabitants either emigrating in haste to milder countries or leading thenceforth the lives of Eskimos. A still more striking reason for leaving the great desert alone is presented in the argument that, by the displacement of so many billions of tons of water, the equilibrium of the earth would actually be affected, and that the engineer who had undertaken the task of adding a new sea to the map of the world would forever afterward be cursed by humanity for having altered the axis of the globe.

On the other hand, various savants consider that these objections are illusory; that the possibilities prophesied are much exaggerated. These men are rejoicing in "another magnificent idea originated in that country which conceived the Suez and Panama canals." The time is near at hand, they claim with enthusiasm, when "the parched ground shall become a pool" and "the desert shall blossom as the rose," as foretold by the Hebrew seer centuries ago.

Considering the broad interest and influence to be established by the undertaking of such a scheme, and the remarkable confliction of opinion concerning its effect, some popular statement of Saharan conditions is apropos at this time. The frigid zones and the "Highlands of the World" have occupied so much of the public attention during the past few years that only the vaguest thought has wandered toward this "last of the unexplored places." As a matter of fact, however, there is no more interesting region on the earth than the great desert of Africa, nor one about which so little is generally known, nor concerning which so many fascinating myths are told and believed. Since the earliest records of history it has been a place of sublime mystery, of dread and weird terrors, of strange and impossible happenings. From the pyramids all the way across the continent to the Atlantic Ocean it reaches—and what is it like, what fearful secrets does it hide? In reality, the Sahara is not so fearful as it is grand and wonderful, as the ocean is wonderful, or any other expression of nature on a gigantic scale, and like the ocean it can be tamed to the service of mankind if approached in proper fashion.

Notwithstanding the fact that the desert has been traversed from time immemorial by native tribes carrying fruits and silks and costly woods and ivory for barter from center to coast settlements, and still is crossed at certain points by important caravan routes, it is even to-day almost entirely unexplored by civilized men. Sir Lambert Playfair, Dr. Erwin von Bary, De Lenz and a few others have partially explored certain portions of it during the past twenty-nine years, yet there still remain large tracts of the territory that have never been viewed by the eyes of any white man.

Topographically, almost the whole northern half of Africa is a desert, in which Egypt and fertile mountainous tracts along the Mediterranean may be regarded as large oases. Geographically, there are three deserts—the Nubian, bordering the Red Sea and reappearing across the sea in Asia in the Arabian Desert, the Libyan, between Fezzan and Egypt, and Sahara or the Great Desert, which includes a number of small arid tracts that extend like long arms far into the fertile regions north and south of its principal body. The last presents a vast undivided waste almost two thousand miles in length from east to west, and nearly one thousand in average breadth from north to south. This means an approximate area of 3,595,500 square miles, one equal to the whole of Europe, without the Scandinavian peninsula. Politically, the Sahara belongs to the various countries which border it or which exercise a protectorate over lands that lie near. Hence, Morocco, the Turkish Empire, Italy, and, through Algeria and Tunis, France, own each its neighboring portion; but by far the chief part of the territory belongs to France along with the French Kongo and the colony on the Senegal.



Map of North Africa and the Great Desert, showing the topography that would shape the Sahara Sea.

The Sahara Desert has several very curious features. The most remarkable is, perhaps, its distinctness of boundary. Standing on the southern slope of the Atlas range, one looks out upon what has almost the appearance of a boundless sea, which forms, as it were, a bold coastline along its northern edge, whose sheltered bays and commanding promontories are occupied by a series of towns and villages. Toward the south, as in Morocco and Algeria, the desert comes to a close in some localities as suddenly as if it had been cut off with a knife, in others it merges gradually into the well-watered and fertile lands of the Soudan. This sea-like aspect of certain portions of the Sahara has given rise to much popular misconception as to its general appearance, and has even affected the ideas and phraseology of some scientific writers. It is not at all the low sand-plain that it is widely supposed to be. It is rather a region of the most varied surface and irregular relief. Rugged hills of barren, rocky formation, known as *hammada*, plateaus of firm clay, mighty fields of loose stones and water-worn pebbles, shallow basins filled with very salt water, and arid steppes covered with sage brush are interspersed with the famous sand-dunes which give character to this remarkable region. Those terrible expanses of shifting sand so fine that it actually penetrates the skin of the traveler and makes breathing distressful lie chiefly toward the east, in the Eastern Erg, as it is called. In the Libyan Desert there are such expanses of vast and unknown limit. In the Western Erg from the Atlantic coast to south of Cape Blanco a broad belt of dunes called Igidi or Gidi—from the Berber word for *dunes*—extends thirteen hundred miles northeast with a breadth of from fifty to three hundred miles.

This is the region which from the highlands of Algeria and Morocco looks so much like a storm-tossed sea. The dunes in all parts of the Sahara lie generally in long undulating lines, very like the billows of the ocean, with gradual slopes to windward and an abrupt descent leeward. They are usually sixty to seventy feet in height, but are said to attain in some places fully three hundred feet. The sand that forms them is exceedingly fine, being, in fact, the dust of rock battered and powdered by the action of centuries of fierce winds and rainless heat by day and sharp chill by night. In this condition every slightest breeze is sufficient to raise it in choking clouds, though the amazing reports of frightful sand-storms which overwhelm whole caravans being the common thing in the desert are mere fairy tales. Under the influence of the winds, all the dunes are subject to a certain amount of continual change, of course, but their equilibrium is such that in topographic distribution they are comparatively permanent. Some of them even have names of their own, like the Gern (peak) al-Shief and Gern Abd-al-Kader to the south of Golea in Algeria.

The color of the sand dunes *en masse* is a rich golden hue, which glints and gleams in the glare of the sunlight with a dazzling strength. Each individual grain is reddish-yellow from the presence of iron, and generally crystalline from having once formed a part of soft quartz rock. Gneiss and mica schists, granite, limestone, slates and basalt all appear in the rocky formation of the Sahara, but the relative proportion of their distribution is not yet fully known. In the central part of the desert south of Algeria there are large extents of red sandstone formations, whose dust carried seaward by the winds is said to produce the peculiar red sky effects noticed sometimes over certain parts of the Atlantic, and notably over Algeria, whither artists journey from every quarter of the earth to study and copy the marvelous combination of rich crimsons and purples and amber. Such sand—produced by the fracturing and crumbling of the cliffs through alternate daily heat and rapid radiation at night—is an active agent of the winds in abrading. In many places it has planed the flat rocks of the *hammada* as smooth as ice. Elsewhere it has scored the vertical faces of the cliffs with curious imitations of glacial striation and has helped to undercut the pillars or table-like eminences which, under the name of *gurs* or "witnesses," are among the most familiar products of Saharan erosion.

As to the elevation of the Sahara, some responsible general estimates have been made within the past few years. The Upper Sahara consists of a rocky plateau, never less than thirteen hundred feet high, which rises at times in considerable peaks; the lower, to which the plateau descends by a steep slope, is a vast depression of clay and sand, usually from two to three hundred feet above sea-level. Scientific investigation of the desert has shown that the soil there lacks no element

Information on Plumbing.

To the Editor of the SCIENTIFIC AMERICAN:

"A Plumbing Improvement Wanted," page 113, issue of February 3rd, 1912. Please inform "master plumber" that he should make a globe of thin copper, then cover with India rubber for the valves. These would float all right and resist external pressure, and the outer covering of India rubber would make the water-tight joint when required.

The Laxey Waterwheel

To the Editor of the SCIENTIFIC AMERICAN:

In your issue of April 19th, page 356, referring to the Laxey waterwheel, you state that it was built about 1865.

I went to the Isle of Man in June, 1859, and went to Laxey in September to visit the lead mines there, and at that time the great wheel had been at work some few years; how many, I cannot now remember, after such a long lapse of years. The above date is the more fixed in my memory, as I was then a boy of eighteen, and this journey to the Isle of Man was my first job.

Restraining the Floods

To the Editor of the SCIENTIFIC AMERICAN:

I have been a subscriber many years. Just finished your article on the Mississippi River (May 25th, page 475). You have a very good illustration for a levee.

The writer piloted on the Mississippi River and the Illinois River fourteen years. Lived in Cairo, Ill., forty years. Was mayor of that city from 1895 to 1897. In 1898 took a trip through Europe. Noticed in Germany the farms were ditched in zigzag fashion; ditches from eight to ten feet wide and about same depth; many miles across the country. They plant willows all along the banks of the ditches. The young sprouts are made into trunks and baskets, which is a very large industry.

These ditches really form a grand system of irrigation. The crops looked fine—healthy and abundant. Water runs along slowly, avoiding the rush of the water into creeks, and rivers have water all summer. In our country we dig straight ditches, which produce overflows during spring freshets, that increase each year as the lowlands are opened up for cultivation. I can remember rises at Cairo, Ill., with high-water marks of 45, 47, 52 feet, and this year 54 feet from low-water mark, a steady increase each flood year.

When you think of making levees in the years to come, I doubt if the States or Government combined can build levees of sufficient height to protect the Southern States, without bankrupting the States and the Government; and with the best of levees there is a continual danger of breaking some of them.

Lockport, N. Y. C. R. WOODWARD.

The Wireless Meddler Again

To the Editor of the SCIENTIFIC AMERICAN:

While the question of amateur interference on the Atlantic coast is under discussion in your correspondence columns, I feel that it might not be amiss for me to add what information I can as to the situation on the Pacific coast.

Amateur stations are as plentiful in the neighborhood of San Francisco Bay as anywhere in the country, and I cannot but feel that the conditions here are a fair example of what is to be met in any part of the country.

I had the good fortune to be listening in at the time of two separate distress messages from vessels here. On the first occasion, the steamer "Beaver" had rammed the Norwegian tramp "Selja" and barely succeeded in rescuing her crew before she sank. The "Beaver" herself was badly damaged, so that the captain felt it prudent to call for aid. At the first S.O.S., nearly every station, amateur and professional, within receiving distance started to answer, but within three minutes of the first call for help, the United Wireless station at San Francisco had a clear line, and was exchanging messages as fast as the apparatus could be worked. Amateurs who started to work during the distress messages were so promptly silenced by other amateurs in their neighborhood that the interference from this source was almost negligible. The main interference came from other commercial stations, who were ignorant of the nature of the business being transacted at the time. Interference was also caused by both stations of a wireless telephone company in the locality, who refused to stop operating until called upon several times to do so. To my mind, the first restrictions to be placed upon wireless work of any kind should fall upon these wireless telephone companies, since the range of disturbance that they create is far greater than that of the average amateur.

The other distress message which I happened to hear was from the steamer "Queen," which had caught fire in the foreward hold. The messages in this case were given religious consideration by all amateurs.

Either the navy stations on this coast differ widely from those on the Atlantic, or somebody is mistaken when they claim that apparatus in such places is antiquated. I know of no better apparatus than the Telefunken sets now being installed at the Government stations. And as for operators, the average Government man, on this coast, at least, can rank with the best in the world. In any station, however, local interference may at times prevent the reception of messages clearly audible at some other nearby station. I think this will explain Mr. Powell's statement in regard to this matter.

Legislation on this subject should only be undertaken with a full knowledge of existing conditions, and of how to better them, and petitions signed by those entirely ignorant of the situation should not be granted any weight in deciding this matter.

Berkeley, Cal. FRANK RIEBER.

High Speed Through the Ice Fields

To the Editor of the SCIENTIFIC AMERICAN:

The editorial upon this subject in your number for July 6th, with its conclusion that high speeds will probably be maintained in the future, raised a line of thought in my mind which I have not seen heretofore discussed. The iceberg which was fatal to the "Titanic" was, I believe, discovered by her lookout about 30 seconds before she struck it. The "Titanic" was traveling at a speed of 22 knots, and the berg was, therefore, originally seen at a distance of 1,100 feet.

Let us first assume, what is approximately the fact, that the radius of curvature of a vessel's track, when her rudder is turned, is the same at all reasonable speeds. Then if the rudder of the "Titanic" had been instantaneously turned, it would have made no difference at what speed she was going, she would have followed precisely the same course, although the amount of damage inflicted would naturally have differed somewhat with the speed of collision. If at less speed the radius of curvature were somewhat larger than at high, which is really the case, the berg could have been more surely avoided at the higher speed.

The point which I wish to raise, however, is that the rudder could not possibly have been instantaneously turned. After the lookout first glimpsed the berg through the darkness, it took him an appreciable time, let us say 5 seconds, to make up his mind that it really was a berg, and to shout to the officer on the bridge. To attract the officer's attention, for him to receive the information, and to step to the engineer's signal, required let us say 5 more seconds. To call the engineer's attention, and to transmit the signal to change the course of the ship required, let us say 5 seconds. To turn the lever and shift the rudder by the required amount required, let us say, 5 more seconds; 20 seconds in all, out of the possible 30. Some of these estimates may be too large, and some too small, but the total 20 seconds cannot be very far out of the way. The ship, therefore, had 10 seconds left, after the rudder was completely turned, in which to change her course.

If now she had been going at half speed the berg would still have been sighted at 1,100 feet distance, but it would have taken the ship 60 seconds to reach it, and the vessel would have had 40 seconds in which to make the turn to avoid it. When she first began to turn she would then have been twice as far from the berg, and since for small arcs the deviation, 1—*cos*, varies as the square of the arc, had she followed the same radius of curvature, at the end of the 1,100 feet she would have been four times farther from her original course than if she had gone at full speed. Even if the radius of curvature of her course were twice as great, she would still have been twice as far from her original course. This would certainly have saved the ship.

Mr. Ismay's point that the higher the speed the less the danger, because the ship would the sooner be through the danger zone, does not appear tenable to the writer. As applied to fog there is undoubtedly an element of truth in it, because one of the dangers of fog is that of being run down by other fast boats. The longer you stay in a foggy region the more boats will cross your track. A slow boat should get through a fog just as quickly as she can. With ice this is not the case, since the speed of the ice compared to that of the ship is so small as to be practically negligible. We may consider it merely as so many islands. All the danger depends on the ship herself. Consequently, the element of time does not enter at all, only distance. Whether she is but one hour or ten hours in the ice is equally dangerous, provided her course is the same.

In conclusion, I would like to add that while the large boat is undoubtedly more economical to run, more stable, more luxurious, and in some respects safer than the small one, yet when it is a question of either fog or ice, the smaller one has the distinct advantage that while the obstacle is visible from both ships at the same distance, the smaller one can in the same time, even if going at the same speed, change her course through a greater amount to avoid it, and is, therefore, in this respect the safer of the two. A smaller boat could undoubtedly have avoided this particular berg.

WILLIAM H. PICKERING.

The Cause of the Quimby Accident

To the Editor of the SCIENTIFIC AMERICAN:

You will recall that in the July 20th issue you published my account of the Quimby accident. Underneath it you gave the substance of a conversation with Miss Quimby's mechanic.

In spite of the general misunderstanding on this Quimby accident, I believe there was never anything clearer. Let me furnish you some further evidence.

When I went in the boat to examine the wreck of Miss Quimby's machine I asked Capt Chase, acting chief signal officer of the United States Army, if he would accompany me, as he had been sent by the Government to pick up whatever he could at the aviation meet. He did so. As we were rowed out to the wreck he asked me whether I noticed that the machine had turned to the left and that Miss Quimby and Mr. Willard were not only thrown out, but to the right. I said that I had noticed this. Mind you, all of this occurred before we had seen the wrecked monoplane. In other words, we had both agreed that the machine turned to the left just as it plunged downward.

When we reached the wreck I scrambled on top of it, and the first thing I saw was the rudder wire caught over the lower end of the warping lever. The mechanic had come out in another boat, and he, too, climbed onto the wreck. I pointed out the caught wire to him, and he held up his finger, and said, how did I know that the wire was caught in the air? He went on further to say that he believed it had been caught after the machine struck the water or on the way down. I replied that of course that question could never be settled, but the fact that it was so caught proved defective design. He then, in the presence of myself, Capt. Chase, and Mr. Thorndike, who rowed Capt. Chase and myself out in his little boat, unhooked the wire from the lower end of the warping lever.

I cannot see how he could be so short-sighted as to say that he did not do this, or that the warping lever was not caught.

In my own defense I have written to Capt. Chase and Mr. Thorndike and asked them to give me an affidavit stating that the wire was caught as I indicated. I inclose copies of the affidavits.

If you examine my sketch, you will see that by the wire catching as indicated the rudder would be thrown to the left and the monoplane turned toward the left as it plunged downward. Does it not seem that it is something more than mere coincidence that both Capt. Chase and myself agreed before we knew anything about this caught control that the aeroplane turned to the left?

I have plenty of evidence to prove that the wire was caught as I say, and it seems to me that the circumstantial evidence goes to prove that it was caught in the air. However, there is one thing that is certain, and that is that the machine should not have been constructed so that the wire could have become caught under any circumstances whatever.

In justice to myself I would much appreciate it if you will publish this affidavit of Mr. Thorndike's with the statements which I have made in this letter regarding the fact that Capt. Chase and myself both agreed the monoplane turned to the left before we knew anything about the controls being caught.

The idea of Willard jumping out or falling out is all nonsense. As the tail of the machine went up and to the right he was thrown out twenty-five or thirty-five feet as a hundred witnesses will testify. The fact that he went much further than Miss Quimby is, of course, easily explained when one realizes that he sat nearer the tail than she did, and because he went so far it gave the idea that he jumped. Assuming he had wanted to jump from a monoplane moving seventy miles an hour, he could not have jumped twenty-five feet. With the wind resistance against his body it would have been about all he could do to flop over the side of the machine, but as it was he was thrown far up and out, while Miss Quimby went below him.

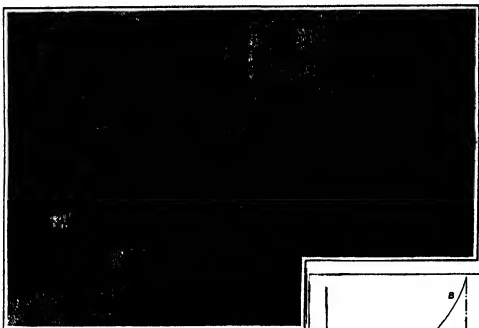
Newton Highlands, Mass. EARLE L. OVINGTON.

[The affidavits of Mr. Thorndike and Capt. Chase, referred to by Mr. Ovington, have been received. They agree with his account. Lack of space prevents our publishing them.—EDITOR.]

What is a Hydroplane?

The Evolution of a New Type of Craft

By Joseph B. Baker



A type of hydroplane without a sharp forefoot, and planing.

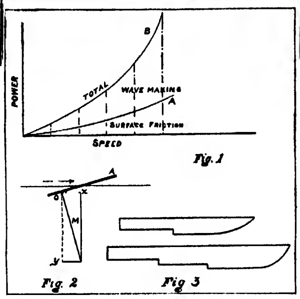


Fig 1.—Diagram indicating roughly how the power required to drive a boat rises with the speed, due to wave-making of immersed surface Fig 2.—Diagram showing the upward thrust due to motion of plane at an angle with the resisting medium Fig 3.—Single-step and two-step hydroplanes.

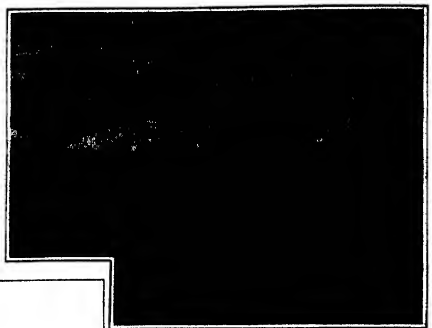

A type of hydroplane with a sharp forefoot, and planing.

THE attainment of high speed in water craft has been a fascinating problem ever since man began to venture upon the water. The oared vessels of the ancient maritime peoples, propelled by many galley-slaves laboring at banks of oars, the triremes in which the sea battles of the Greeks and Romans were fought, the speedy oar and sail ships of the Norse Vikings, the war canoes of the American Indians, were all pushed hard upon occasion, to get the utmost possible speed But these craft one and all were creatures of limitation; the boat, man's water-going invention, could not hope really to command the sea until steam became available for marine propulsion, replacing human muscle and the capricious aid of the wind by a mechanical power which could be increased indefinitely

The application of steam opened up a new era; but though vessel speeds were greatly increased, the ability to eat up the miles on the water as the railroad train does on land was by no means attained It might be thought that the speed of an engine-driven vessel would be merely a matter of motive power—that in order to increase the speed one must simply put in a larger, more powerful engine. But such is not the case, as the designers of steam craft in the first few decades following Robert Fulton's great demonstration soon found out So far from the speed of the vessel being proportional to the engine power, or in anything like that ratio, it was found that above a certain speed—depending on the design of the hull—it did little good to increase the power The work of the engine, delivered through side wheels, stern-wheel or propeller, was expended in urging the mass through the water on which it floated The ordinary boat is a structure which sinks till it has displaced a weight of water equal to its own weight, and in all boats this means that the immersed surface presents a considerable resistance to the forward urging of the wheels or propeller Shaping the surface to give the easiest possible passage through the water, by refinements of marine architecture based on the study of stream lines, fluid friction and the friction of the supporting fluid on the surfaces of the immersed part of the hull, reduces this retardation. But with the easiest sliding hull that could be built to give the required displacement consistent with seaworthiness, there is an inevitable limit to the increase of speed with increase of power—a limit beyond which it does not pay to put in a larger engine simply because at most a trifling increase of speed is obtained thereby. Any attempts to exceed this "critical speed" result in an abnormally heavy and bulky motive power and correspondingly great weight of fuel required to be carried and space alloted to fuel, a condition inimical to cargo carrying capacity and sometimes also to seaworthiness, and permissible only in war vessels and racing boats, where high speed at any cost is the ruling consideration.

The introduction of gas engines as motive power, giving rise to that remarkable product of the past fifteen years, the motor boat, helped the speed problem wonderfully by enabling a much larger power to be realized from a given weight and space of material in the engine and in the fuel carried (gasoline). Motor boats have set an entirely new standard of marine speeds through the use of an engine which is of small weight and size compared to the steam engine with its boiler and coal, and which allows the hull to be designed with finer lines. But notwithstanding the extension of the speed possibilities thus gained, the fluid resistance of the hull as an immersed surface largely remains to limit the speeds attainable. In brief: As long as the craft presents a considerable immersed surface it must be driven *through* the water, and, therefore, encounters a resistance which rises very rapidly with the speed. Without dwelling on technicalities we may note in passing that the fluid resistance to a boat's motion is made up of two parts, viz., surface friction and wave-making. As shown roughly in the annexed diagram (Fig. 1), whereas the surface friction (the lower ordinates) increases as the square of the speed, the power consumed in wave-making increases very much more rapidly, that is, at an increasingly rapid *rate* of increase. This wave-making resistance is due to the displacement of water by the moving boat.

But if one can avoid driving the craft through the water at all? If we can drive it *over* the water we can largely reduce the displacement resistance, which cuts such a figure in an immersed boat, and at the same time very considerably reduce the skin friction, making our curve of power consumption approximate curve *A* with short ordinates, since the immersed surface is much reduced. Then we shall be utilizing the principle which keeps a well-thrown "skipping-stone" flying for a long distance over the water, just as the aeroplane utilizes the principle which keeps a kite aloft.

The very consciousness of a need leads to its supply. The step from the ordinary boat to the hydroplane has been taken in response to the need of higher speed on the water, just as the step from the balloon to the aeroplane was taken in response to man's need of control and speed in the air. Both of these improvements have come from abandoning the supporting quality of mere volume displacement, and utilizing the supporting quality due to resistance to a plane driven at high speed. The hydroplane has a bottom structure which, though heavier than its displaced water, yet stays on the surface like a skipping-stone by constantly moving

"Elcoplane," the great rival of "Dixie Jr."

"Vita Jr.," the latest 1912 type. Note the front rudder.

on the water; the aeroplane is a heavier-than-air structure which stays up like a kite by continually moving against the air. The hydroplane is upheld because its velocity develops a sufficient upward thrust of the water over which it is passing, just as the aeroplane is upheld because its velocity develops a sufficient upward thrust of the air through which it is passing.

The hydroplane is a vessel designed for two features of performance: 1. To rise out of the water when driven, owing to a very strong upward thrust on its hull and a light total weight which the upper thrust can lift. 2. To offer the minimum friction resistance at speed. These features, in a craft having a powerful gasoline engine and manned by a competent crew, result in high speed. The hydroplane is driven faster than an ordinary boat, by an engine of given horse-power, because it is lifted up on top of the water and kept there; the power of the propeller exerted to drive the craft ahead also develops an upward thrust on the hull by reason of the plane bottom of the hull. Let us look more closely at this matter of upward thrust. Consider a heavy plank or plane, driven through the water in a direction making a slight angle with itself. The total resistance to the direction of motion may be resolved into components, one parallel to the plane and one normal to it. The former involves the skin friction; it is the latter which involves the levitating action of the plane. Let A, Fig. 2, represent the plane, and M this normal component which we may resolve into two components Ox, a horizontal drag tending to retard the motion of the plane, and Oy, a vertical lift on the plane. If now the speed of the plane is high enough in proportion to its weight, that is, if this component Oy is great enough to lift the weight of the plane, the latter will rise. The diagram shows that in order to obtain an advantage from the use of such a plane fixed on the bottom of a vessel, the benefit of the lift due to the plane must outweigh the drag and friction of the same—the latter diminishing, of course, as the craft rises on account of the diminution of immersed surface. It is all a matter of the ratio of the power of the craft to its weight. The idea itself is not new: plane boats equipped with powerful steam engines had been built before the present hydroplanes, but until the gasoline engine with its high weight efficiency was applied to motor boat propulsion, the weight of the power plant and of the hull required to contain the same was too great for the lifting force.[1] With the gasoline engine, itself of light weight for large power and capable of installation in a light hull having a bottom designed with one or more planes, the lifting energy was able to force the structure up out of the water; and the characteristic high speed of this craft at once resulted, owing to the reduction of wave-making and surface friction.

It is instructive to trace the performance of the hydroplane, its position with regard to the water as the speed is increased from zero to the maximum of which the vessel is capable. Take the simplest construction, the so-called monoplane (upper sketch, Fig. 3). At rest, this craft floats in the water like any other boat, being supported by its static buoyancy. When the engine is started, the resistance of the plane bottom causes the bow to rise; but ordinary buoyancy is still the ruling factor, and the stern sinks until the additional immersion of the after part displaces enough volume of water to support the boat. As the speed increases, the further rising of the bow moves the center of upward thrust back, until it reaches almost to the center of gravity of the craft. At this stage of the speed, since the point of support is very near the center of gravity, the boat is ready to pivot vertically, so to speak, upon this point; and with further increase of speed the boat, powerfully upheld by the vertical component of the fluid pressure on its bottom, drops its bow, but raises its stern, till its bottom rests on the surface of the water at a small angle therewith, and with very little displacement of water compared with that in the position of the boat when at rest. The main factor is no longer static buoyancy, but the new lifting force due to the speed of the boat. This is the planing position, the power of the engine is showing a speed which could never be attained in an ordinary boat with a displacement hull. If the speed is still further increased, the bow may be sharply depressed, causing the craft to dive headlong. The hydroplane may be built with a single plane or "step" or it may have two or more steps, as shown in Fig 3. These are over-water hydroplanes. A type in which the upward thrust is given by totally immersed planes has been successfully demonstrated by Mr. Peter Cooper Hewitt in this country and by Signor Enrico Forlanini abroad. It is to the over-water hydroplane that we owe the phenomenal advance in boat speeds in recent years. The 21 miles per hour of the "Vingt et un" ten years ago, a speed unheard of up to that time, has to-day been more than doubled, the "Dixie IV," the fastest boat in the world, making 46 miles. Attention to detail, refinement of design and the cutting down of weight enables this American-built craft of 500 horse-power to beat foreign boats having over 800 horse-power. The same speed qualities are shown in smaller boats of this type also; a craft new this year and only 20 feet long has shown a speed of 38 miles per hour.

The average of five runs in a speed trial of the 20-foot "Dixie, Jr.," hydroplane, over a course one mile long in Newark Bay, June 21st, showed a speed of 43 13 miles per hour, the best performance being 1 minute 22 1/5 seconds for the run north, which figures out 43.78 miles per hour. It is safe to say that this speed is as fast as any 20-footer has ever traveled. This boat is owned by Mr. Harry Payne Whitney. Next year may show us 50 miles per hour in a 40-foot boat. The use of the Government tanks at Washington, D. C., for testing out large-size models has been of great assistance in developing the lines of these vessels. This year will see our British cousins here again—their challenge has been received—to try to win back the Harmsworth trophy; and there may be other foreign boats in the contest. Will some scientific American prove equal to the task of defending it?

A hydroplane at low speed, not planing.

20-foot "Dixie Jr.," with a speed of 43.78 miles per hour.

[1] Nearly fifty years ago Mr. Ramus, a clergyman, conceived the idea of driving vessels over the water instead of through it, and tried his scheme in the British Admiralty experimental tank at Torquay; but it failed because of the poor ratio of power to weight.

The Value of Radium

THERE are no very exact statistics of radium available, but according to the United States Geological Survey the whole quantity in the world is probably not over two or three ounces, and its value, like that of the big diamonds of the world, is purely nominal. It is worth whatever the possessors can get for it. The head of the English corporation producing radium claims that it is worth approximately \$100,000,000 a pound. A year ago this same person had estimated the value of radium at one third more. However, a little variation of \$50,000,000 is not thought to matter where there is no appreciable fraction of a pound of the precious stuff in sight. The fact that has more than anything else to do with fixing the price is the existence of several radium banks in the world where tubes containing a microscopic speck of radium are rented out to doctors at something like \$50 a day. While it is known to be of some value in treating lupus, which is a form of tuberculosis attacking the tissues, usually of the face, there is little else known about its medical value. It has been claimed on several occasions that radium was valuable in the treatment of cancer, but experiments have not proved this to be an absolute fact.

A short time ago it was reported that the Austrian government had purchased the only two mines under private ownership producing the ores from which radium is made, and thereby gained a monopoly in its manufacture. This report, however, turned out inaccurate. It is true that the Austrian mines and the Austrian government heretofore have supplied the bulk of the radium salts existing in the world, but at the present time radium is being manufactured in three other countries, the United States included. Sweden is producing radium from kolm, the English are getting it from mines in Wales, while we get it from western Colorado, where there is a large deposit of radium-producing ore. These deposits produce also uranium and vanadium, the latter being used for making some of the high-grade steel alloys. While the mining pays in vanadium alone, the ore produces a certain per cent of radium. Ten tons of it procure only between twenty and thirty milligrammes of radium.

The Flight of Projectiles

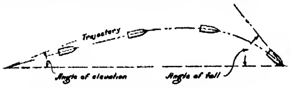
The Actual Positions of a Shell from Gun to Target

By Rear-Admiral N. C. Twining, U. S. N., Chief of the Bureau of Ordnance

"THE axis of a projectile in flight is at all times sensibly tangent to the trajectory." Sketch No. 1 shows the positions which a projectile takes in the different parts of its trajectory.

A large number of persons believe, however, that the axis of a projectile in flight remains parallel to its direction when fired. These persons believe the positions of the projectile to be as shown in sketch No. 2.

It will be sufficient for the present to state that these persons (of whom there are a surprisingly large number) are wholly in error, and that a projectile in flight cannot possibly take the positions shown in sketch No. 2.



Sketch No. 1.—Shows actual position of projectile during flight from gun to target.

The discussion as to whether sketch No. 1 or sketch No. 2 is correct has continued for many years, and has long been considered a moot question. It has frequently been stated that authorities differ on this question. This is not quite true, for it will be found on investigation that all "authorities" are of the same opinion. There is absolutely no doubt that the believers in sketch No. 1 are correct, and that those who believe in sketch No. 2 are in error.

It is important to establish the correctness of sketch No. 1, as many articles and criticisms have been written on the premise that sketch No. 2 is correct, and consequently a great deal of mis-information has been placed in print, and a great many incorrect deductions have been made.

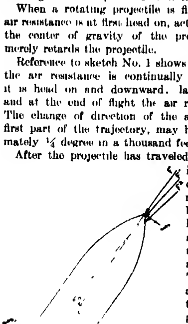
In investigating the flight of projectiles, it is not apparent why so many have been led to believe that sketch No. 2 is correct. There is neither theory nor fact to support such belief. It is stated that owing to the "gyroscopic principle," a projectile will remain parallel to its original direction. The assumption is wholly incorrect, for although a rotating projectile is a gyroscope, there is no gyroscopic principle which allows a projectile to remain parallel to itself while it is being acted on by the force of the air resistance.

Sketch No. 2. False idea of positions of projectile during flight.

When a rotating projectile is fired from a gun, the air resistance is at first head on, acting in a line through the center of gravity of the projectile. This force merely retards the projectile.

Reference to sketch No. 1 shows that the direction of the air resistance is continually changing. At first it is head on and downward, later it is horizontal; and at the end of flight the air resistance is upward. The change of direction of the air resistance in the first part of the trajectory, may be taken as approximately ¼ degree in a thousand feet.

After the projectile has traveled a short distance in its trajectory the direction of the air resistance changes, bending toward the horizontal, the resultant force striking the projectile as at F', sketch No. 3. The force F' does not act through the center of gravity of the projectile, but forward of it, creating a small overturning moment, or "gyroscopic moment," represented by $F'a$. If there were no rotation this moment would tend to overturn the projectile; but as the projectile is rotating, the overturning moment causes the projectile to begin to precess about a line passing through the center of gravity of the projectile and parallel to the direction of the force F'. This line is sensibly the direction of the trajectory.



Sketch No. 3.—Air resistance against projectile during flight.

The force F' strikes under the point of the projectile, and if the projectile has right-hand rotation, it will start precessing to the right. The projectile behaves quite like a top that has not gone to sleep. The top is rotating, while its axis is precessing or wabbling. There is this difference, however, that the top makes a number of complete precessions, while the projectile makes only partial ones, as will be explained. It must be understood that owing to the high speed of rotation of the projectile (4,000 to 20,000 revolutions per minute, or even greater), and the relatively small overturning moment of the air resistance, the time necessary to make a complete precession would probably be one or more seconds, depending on the projectile, its speed of rotation, and the overturning moment. If the overturning moment decreases, the speed of the precessions decreases.

Before the projectile has finished more than a part of a complete precession, it has traveled several hundred feet, and the direction of the air resistance has again changed to F'', striking the projectile slightly farther under the point. The first precession is arrested before more than a part of a precession has been completed, and another precession starts about the new direction of the air resistance, the point of the projectile again bearing off to the right (as viewed from the rear). As the direction of the air resistance changes again and again, new precessions are started before previous ones are more than partly completed. The point of the projectile, therefore, describes a series of cusps, the horizontal traces of which are practically cycloids, appearing somewhat as shown in sketch No. 4. The point of the projectile for right-handed twist remains for the most part to the right of the vertical plane of the trajectory.

The overturning moment (which depends on the air resistance and the lever arm) is balanced in a sense by the speed of the precession. With a given speed of rotation of a projectile, if the overturning moment decreases, the precessions become of greater period. As the changes in direction of the air resistance are relatively small, and as new precessions are started with every considerable change of direction, it follows that the amplitude of the precessions is small, and the axis of the projectile never diverges more than a few degrees from the trajectory.

As the projectile reaches the latter part of its trajectory its speed of rotation diminishes but slightly, while the overturning moment falls off very greatly, due to the large reduction in the air resistance. The precessions in this part of the flight are, therefore, slower, and of greater amplitude. This is indicated in sketch No. 4.

In addition to the overturning moment caused by the resistance of the air, there are also frictional forces which oppose the rotation of the projectile. These forces act at right angles to the head-on resistance, and the effect over the whole projectile may be represented by a force at each end of the projectile acting in opposite directions, as shown in sketch No. 3. These forces are the equivalent of a force f-f', acting through the center of gravity, and a couple tending to depress the axis of the projectile toward the trajectory.

As soon as the axis of the projectile becomes tangent to the trajectory, the friction forces disappear, as the friction then becomes symmetrical about the axis.

The force f-f' moves the projectile bodily sidewise, and is one of the elements causing drift. The friction couple assists in keeping the axis of the projectile tangent to the trajectory.

This friction force is quite like the friction acting on the peg of a top. The axis of the top is finally brought into line with the direction of the force of gravity by the friction on the peg acting at right angles to the force of gravity.

There is absolutely no proof, theoretical or otherwise, that a projectile in flight will remain parallel to its direction when fired, while the theory of gyroscopes shows plainly that the direction of the axis of the projectile must depress continually to meet the changing direction of the air resistance.

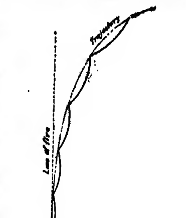
In addition to the theory, the following tangible proofs show conclusively that the axis of the projectile is at all times sensibly tangent to the trajectory:

(a) Cardboard impact.
(b) Photographs.
(c) Reports of observers.
(d) Reproduction of motions with air currents and model projectile.
(e) Penetration of armor.
(f) Retardation of velocity in flight.
(g) Explanation of drift.
(h) High-angle fire.

Cardboard Impact.

It is evident that if a projectile in flight should hit a target which offered practically no resistance, the projectile would pass through the target without being deflected, and would make in the target a hole indicating the position of the projectile in flight.

In October, 1909, at the Naval Proving Ground, Indian Head, Md., firing took place with an 8-inch gun at a cardboard screen, the range being 7,600 yards. The angle of elevation of the gun was about 9 degrees, 30 minutes, and the angle of fall 13 degrees, 45 minutes. Reference to sketch No. 5 will show that if the projectile had remained parallel to its original direction, an oblong hole would have been made in the cardboard about 15.35 seconds in length. The hole actually made in the cardboard was practically circular, having a diameter of about 8.23 seconds. This evidence is conclusive that the axis of the projectile must have been practically tangent to its trajectory.



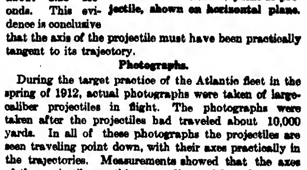
Sketch No. 4.—Path of point of projectile, shown on horizontal plane.

Photographs.

During the target practice of the Atlantic fleet in the spring of 1912, actual photographs were taken of large-caliber projectiles in flight. The photographs were taken after the projectiles had traveled about 10,000 yards. In all of these photographs the projectiles are seen traveling point down, with their axes practically in the trajectories. Measurements showed that the axes of the projectiles at this range diverged less than 2 degrees from the tangents to their trajectories.

Reports of Observers.

Many observers at target practice, and at other firings, have reported seeing projectiles in flight striking with their points following the trajectories. In no instance has any report been received of a projectile falling point up, as in sketch No. 2. Observers of mortar firing have reported that the axis of the projectile, both in the ascending branch and in the descending branch, follows the trajectory.



Sketch No. 5.—Showing by impact of projectile on card, actual position during flight.

(To be continued.)

Loetschberg Tunnel Approaching Completion.—The Loetschberg tunnel, which has been driven through the mountain on the right bank of the Rhone, and which will form an outlet from the Simplon tunnel to the northward, is practically completed. The tunnel carries a double-track railroad and is lined throughout its full length, which is slightly over 9 miles, or 47,??? feet.

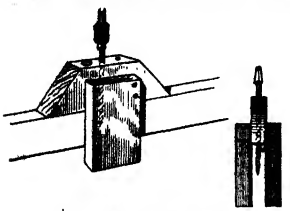
Suggestions for the Workshop

Ingenious Expedients of Resourceful Mechanics

Gage for Boring Dowel-pin Holes

By William Grötzinger

IT is often a difficult matter to bore straight dowel-pin holes in two pieces of wood, which are to fit together squarely and tightly. The following description of a gage for the purpose should be readily understood: It is made from a piece of oak board, with two side pieces screwed so as to form a socket in which the work fits and is held squarely. A number of different size holes are bored into the oak piece, so that bits of different sizes can be used, for large or small dowel-pins. Mark the work with a pencil where the holes are to be bored, put the gage over the work, and put the bit in the holes of the desired size. Be sure to get the bit on the pencil mark, then bore the hole. If the gage happens to fit a little loosely, it can easily be made tight by wedging it with small wooden wedges.

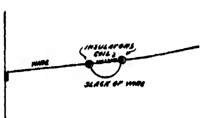


Gage for boring dowel-pin holes.

Reducing Noise of Telephone Wires

By R. D. Mock

A WIRE, especially one with a long span, is sometimes a noisy proposition when it is attached to the clapboards of a house. Every time the wind blows a little harder than usual there is such a moaning and groaning that sleep is well-nigh impossible. The wire seems to make a noise on the principle of the old-fashioned squawker boys used to make out of a tin can with a stout thread fastened to the bottom of it. Pulling the thread would produce a fiendish noise. And every time the wind would make the wire give a pull on the house, it would sound like that old tin can. In my case, the telephone wires were the offenders.



Noise reducer for telephone wires.

The next time a lineman was in the neighborhood I got him to give me about a foot of slack on each line. Two very stiff coil springs and two pairs of porcelain insulators then did the work. Each wire was wrapped around two of the insulators in the regular way and then a spring was inserted between the two, as may be seen in the diagram. The other wire was handled in the same manner. The spring was stiff enough to draw the wire up to nearly its usual tautness, and yet it was elastic enough to take up all the jerks and unusual pulls that formerly made so much noise. Everybody slept much better on blustery nights after this. Of course the main thing is to get a stiff enough spring so that the wind will not pull it out.

A Cheap Pipe Wrench

By H. C. Urbaner

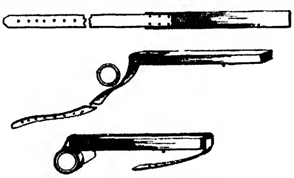
QUITE frequently it becomes necessary to have a pipe wrench, especially for brass tubing, that will not mar the work and yet at the same time will permit of using sufficient force to produce the required results without crushing the tubing.

Fig. 1 shows one of the cheapest, simplest, and yet most efficient of pipe wrenches. It consists of two parts: A piece of hard wood about $1\frac{1}{2} \times 1\frac{1}{2} \times 18$ and a piece of strong 3-inch leather belting about 3 feet long. The strap should be riveted to the wood with the heads well sunk below the surface of the wood on the side opposite the strap side of the lever. The loose end of the strap should have holes punched at intervals of one inch or so to make it adjustable to the work with the stud the opposite side of the bar. The strap should be turned down over the end of the lever, then up and around the work and back along the top of the lever and around the opposite end, where it is fastened to the stud on the under side. The object of throwing the strap around the end of the lever rather than to fasten it at the end is to insure a maximum amount of pull on the strap with a minimum strain where it is fastened to the stud. Use this device like any other pipe wrench. To release the wrench for another pull, simply pull it away from the pipe far enough to allow it to loosen its grip and begin for the new pull by simply repeating the first operation. The end of the strap must not be taken from the stud after it is adjusted until the operation of turning the pipe is completed.

With the use of this wrench, an even strain is placed upon the tubing on its entire surface without any possible danger of marring or crushing it.

With a few trials the work can be done as quickly as with an open pipe wrench.

The writer has employed this idea in many different ways, and finds it most helpful. When a fountain pen



Pipe wrench for polished brass.

cap "sticks" take a little stick and a piece of dampened cord and in a moment it is loose.

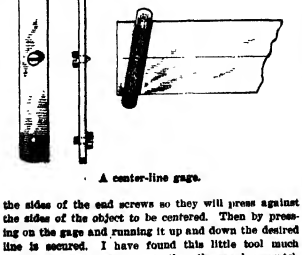
A few years ago the writer had occasion to unscrew the first joint of a 2-inch pipe in a tubular well in order to find the end of a broken wooden rod inside. As no large pipe wrench was at hand one was made as here described from a 4-foot piece of oak scantling and a strip of $1/16 \times 2$-inch hoop iron purloined from a vinegar barrel. After setting the wrench two strong men pulled on the 4-foot lever with all their strength to start the pipe.

Center-line Gage

By Henry Klotz

THE accompanying sketch shows a handy little tool which for want of a better name I call a center-line gage. It is very useful on many jobs, and is easily made as follows: A piece of iron or steel about ⅛ inch thick and 1 inch wide is drilled and tapped to receive three screws as shown in drawing. The point of the center screw can be hardened so as to wear better, but this is not essential, as it can easily be sharpened when dull and replaced in position.

When it is desired to mark a center line on a piece of wood or metal, place the gage over it and bring



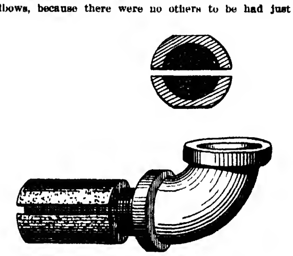
A center-line gage.

the sides of the end screws so they will press against the sides of the object to be centered. Then by pressing on the gage and running it up and down the desired line is secured. I have found this little tool much more convenient and accurate than the regular scratch gage for centering.

Unscrewing Nipples from Pipe Fittings

By G. H. Ander

WHILE doing some pipe fitting the other day, the writer needed some close nipples and was obliged to take apart and use old ones, stuck in tees and elbows, because there were no others to be had just



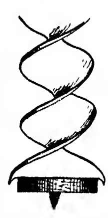
Device for unscrewing nipples.

then. It was impossible to get the old nipples loose with a wrench or in a vise without spoiling the thread, so a pipe-cap of the same size as the nipple was procured. This cap was cut in two with a hacksaw. The two halves were placed on the nipple, after first having filed them flat on the sides, in order to prevent them from turning around in the vise, while unscrewing the nipple. This method proved to be very successful. The nipples came out without any injury whatsoever.

Enlarging a Bore With an Auger

By F. H. Jackson

THE following kink should prove useful for plumbers or gas-fitters. When boring a hole through a joist for a pipe, the auger ran into a knot, throwing it a little out of line, so that the pipe when run through the hole would not screw into the fitting. The trouble was overcome by fitting a small circular piece of wood of same diameter as hole, on the spur of a larger auger which made a guide, and the hole was easily enlarged to a suitable size.



Enlarging a bore.

Shop Notes

Cuttlefish Paper.—Some years ago my attention was called by a professional friend, a dentist, to a paper which is sold by the dental supply houses under the name of "cuttlefish paper," and which is used by dentists to polish gold fillings, it being for this purpose cut into narrow strips, passed between the teeth, and pulled back and forth over the filling. The abrasive material on this paper (which comes in sheets about the size of ordinary sandpaper) is of such a degree of fineness, that it is difficult to tell which side of the paper is coated. The paper, which is apparently practically unknown except to dentists, has other very valuable applications. It is an ideal material for the rapid honing of razors and of surgical and other instruments requiring a fine edge. Its cutting qualities are so rapid that a pocket-knife blade of ordinary degree of sharpness can, by giving it fifteen or twenty diagonal strokes on a piece of the cuttlefish paper, laid flat, and followed by a slight stropping on a leather strop or shoe top, be brought, in the space of a couple of minutes, to such a degree of sharpness that it will remove the hair from the back of the hand or arm as though it were a razor in fine condition. In honing razors, especially those that have a rounded edge and need honing badly, it will produce results in one or two minutes that would require a half hour or more on a stone hone. For this purpose the paper is drawn over a level wooden block, and turned over the ends and tacked or clamped in place; the razor is then laid perfectly flat, and given diagonal strokes in both directions, drawing away from *the edge*. Ten to twenty strokes in each direction will usually be sufficient. A moderate amount of stropping will remove the slight feather edge sometimes produced, and leave the razor in fine condition for shaving. So far as I know, the paper is obtainable only through dental supply houses.—Claude L. Woolley.

Automatic Control for Aeroplanes

AN aeroplane maintains a constant level in the air by maintaining a constant speed through the air If the air is in motion, the matter is complicated by the fact that the winds never move with constant velocity The steadiest of winds is interrupted now and then by a lull, and sometimes a wind is made up of a succession of puffs. An aeroplane when moving in a variable wind, particularly when moving in the direction of the wind, must bob up or down, depending on its velocity with respect to that of the wind. Under these conditions it finds the same difficulty of keeping its equilibrium that one experiences when trying to walk on a shaking platform, such as found in our amusement parks. Conditions would be the same were the machine flying in quiet air, while its engine was retarding and accelerating irregularly. The only cure for its staggering course in fickle winds is to compensate for the retarding and accelerating of the wind by accelerating and retarding the engine to a corresponding degree

As a rule, aviators depend on hearing and touch to determine their speed through the air. But the best of pilots often find it difficult and impossible to account for variations of speed experienced during a flight. The balance of an aeroplane is so delicate that even in still air, it often swerves from unsuspected causes. Capt Etévé of the French army states that more than four fifths of all aeroplane accidents are due to loss or excess of speed, and he believes that it is essential to good flying that the pilot of an aeroplane be provided with an instrument which will show the speed of his machine over the air. He devised a simple instrument of this sort, which is shown in Fig 2.

It consists of an aluminum plate A with a dial sector on which is a prominent red reference mark shown at B. The indicator needle C is secured in a block pivoted at D Rising vertically from this block is a rod, on the upper end of which is a hollow sphere E; a bob F below the block serves as a counterbalance, while a spring G may be adjusted to hold the sphere E in vertical position, and the pointer C on the mark B when the aeroplane is traveling at a certain pre-determined speed. As the instrument moves through the air in the direction of the arrow, the wind pressure on the sphere E causes the latter to swing on its axis D, and depress the pointer C, when the speed exceeds that for which the instrument has been adjusted. On the other hand, if the speed decreases, the spring G causes the pointer to rise above the mark B. This instrument is very sensitive and provides the pilot of the aeroplane with an accurate gage of his speed

The extreme sensitiveness of the apparatus has given the hint to Capt. W. I. Chambers of the United States Navy to employ a speed indicator of this general character for the automatic control of the elevating rudder of the aeroplane Capt. Chambers' instrument is shown in Fig. 1, which is partly broken away to show interior details. Like Capt. Etévé's speed indicator, it is provided with a dial sector B, and a pointer C, connected to a sphere E, which projects in the path of the wind At each side of the safety mark B are arms J bearing contact buttons with which the pointer C is adapted to come into contact when the speed of the aeroplane exceeds or falls below the safety limit The electric circuit is thus closed to elevate or depress the horizontal rudder of the aeroplane The arms may quickly be adjusted by the pilot while in flight to suit any condition

Mounted on the rod which bears the sphere E is the crosshead, from which are suspended upon a pair of very flexible spring bands I, weights K, that are adjustable on stems. The spring G pulls the rod on which the sphere is mounted and its tension is regulated by means of the screw L. A variety of adjustments are thus provided, first, the sphere E; second, the spring G; third, the crosshead H; fourth, the springs I; and fifth, the weights K Thus ample flexibility is assured for the power and the sensitiveness of the pressure sphere and for the power and the sensitiveness of the accelerating action of the weights K, which operate above the axis D.

In a separate compartment of the instrument there is an electric lamp M, in front of which is a slotted cylinder N, which may be turned so as to allow the light to pass through the slot and illuminate the dial sector. This illumination may be made as bright or as dim as desired by rotating the cylinder. Above the instrument a 2-inch barometer O may be mounted, receiving its light through a slit as indicated at P, the light being reflected to the barometer dial from a small semi-circular reflector above its face Thus we have, combined with a flexible automatic stabilizing device of light weight, an effective speed indicator, which is always adjustable to suit the conditions of flight and is always available for use in event of motor derangement

Method of using the pocket sun-dial.

A Pocket Sun-dial

By Dr. Leonard Keene Hirshberg

A NOVEL form of sun-dial has recently been devised by Mr. F. N. Lovegrove of London, England. Not only does this dial give the hour, but by it may be found the time of sunrise and sunset in any part of the country, also the sun's declination and the date of its entry into any constellation of the Zodiac. The sun-dial consists of a sheet of cardboard in the upper end of which a piece is cut out, so that it may be bent up to form a gnomon. When the shadow cast by the gnomon falls on a shadow line drawn on the cardboard, the time is determined by the position of a bead on a plummet line. The plummet line is adjustable in a slot to allow for variations in the declination of the sun at different dates throughout the year. The dial may be laid out as follows:

Draw first a shadow line near the upper edge of the cardboard, and near the middle of the cardboard draw the line AB parallel to the shadow line. Draw a line at right angles to AB, intersecting it at C. Extend this line to intersect the line AD at the point E, the line AD forming an angle with the line AB equal to the latitude in which the sun-dial is to be used. For instance, in New York, which is at latitude 40 degrees, the line AD would form an angle of 40 degrees with the line AB. Through the point E draw the line FG at right angles to AB, and the lines AF and AG forming angles of 23½ degrees with the line AD. With E as the center, describe the semi-circle FDG. Divide the arc into six equal parts and drop perpendiculars to the line FG. From the point F as the center with a radius equal to AF, draw the arc Af, and from the point H as the center with a radius equal to HA, draw the arc Ah and so on. Upon these arcs are drawn the hour lines, which are obtained in the following way: From C as a center with a radius equal to AC, draw the semi-circle AMN; divide this curve along the circumference into twelve equal parts, and from the points of division thus found, drop perpendiculars to the line AB. The hour lines may then be numbered as shown in the drawing. Mark the line Af with the zodiacal sign of Capricornus, and the line Ah with the signs of Aquarius and Sagittarius, the line Aj with the signs of Pisces and Scorpio, and so on with the rest of the arcs. The zodiacal signs may be found in any almanac.

The date line may now be laid out. An arc is drawn at O. This is calibrated in degrees of a circle. Then referring to an almanac for the declination of the sun at different times of the year, the line FG may be graduated to show the various positions of the sun for different months. For instance, the sun's declination on the first of August is 18 degrees north, and on the last of August is 8 degrees and 41 minutes north. By extending lines from A through the corresponding degrees in the arc O, the points where they intersect the line FG will mark the month of August on the date line. This space may then be sub-divided into thirty-one parts if desired to indicate the different days of the month. After the date line has been laid out, a slit is cut in the cardboard along the line FG. The gnomon is also laid out along the shadow line. The lines ab, bc, and cd are cut through, leaving the line ad uncut. On this line as a hinge, the tab of paper is bent up. A thread is now passed through the slit FG, and upon it a bead is fitted. A knot on the thread keeps it from slipping through the slit. The lower end of the thread is weighted with a small piece of metal. The sun-dial may then be used as follows:

If the observation is to be made on July 15th, the thread is moved in the slit to the corresponding position on the date line, and then is stretched across the 12 o'clock point and the bead is moved up to cover this point. Then the dial is held in the sun so that the shadow cast by the gnomon falls along the shadow line. The bead will swing down along the arc Al, and will come to rest over the hour of the day at which the observation is taken. When the plummet line hangs parallel to the line CM the bead will denote the hours of sunset and sunrise for that particular day. By stretching the plummet line across the point A, the declination of the sun for that particular date may be determined on the arc O. As in all sun-dials, allowance must be made for Greenwich time. The difference of longitude must be allowed for at the rate of four minutes for every degree, subtracting from sun-dial time to the east and adding to it the west. For instance, when it is five o'clock on the seventy-fifth meridian, from which time in the eastern section of

the United States is taken, the sun-dial will give the hour as four minutes past five in New York, which is on the seventy-fourth meridian.

The Trade-mark as a Business Asset

By W. E. Woodward

[*THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer; that it is a symbol of good will, a tangible asset with a determinable money value; that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.*

The following is the fifth of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

Analysis of the Requirements for Registration.—V.

(*Continued from page 108, August 3d, 1912.*)

Many applicants for trade-mark registration seem to think that the mere misspelling of a descriptive word, or some fanciful device in lettering, will remove the word from the descriptive class. This is a belief that has no basis in fact; for no matter how a word is spelled or lettered, it is descriptive if it conveys information of a descriptive character.

For instance, the word "Bestok" was rejected as a misspelling of "Best Stock;" "Unxld" as a misspelling of "Unexcelled;" "Kid Nee Kure" as a misspelling of "Kidney Cure;" and "Pittsburgh Pump," printed with hyphens between the letters —P-I-T-T-S-B-U-R-G-H P-U-M-P—was refused registration as being both descriptive and geographical.

The courts have held that the word "Elastic," used to designate drawers having an elastic seam, is descriptive, but the same word is used in a fanciful sense and is valid as a trade-mark when applied to sectional bookcases.

A manufacturer of hooks and eyes applied for registration of the phrase "Rust? Never!" as a trade-mark. Registration was refused, as the mark was held to be descriptive, indicating that the hooks and eyes would never rust.

Arbitrary numbers are obviously registrable as trade-marks, but the applicant must be prepared to establish his contention that the numbers are really arbitrary and meaningless. In certain trades, numbers are used to designate grades of a product common to the trade, and, in that case, the grade numbers are descriptive by common usage. A plow manufacturer applied for registration of the symbols "A No. 1," "No. 1" and "AX No. 1" as trade-marks for plows. It was shown, upon examination, that these symbols are used by many plow makers to designate grades, and they were, therefore, ordinary descriptive trade terms. Registration was refused.

The prohibition against trade-marks descriptive of the character or quality of the product applies with equal force to trade-marks descriptive of the container or package. A flour manufacturer put up his product in barrels of a distinctive character—white and dark staves alternating. He applied for registration of a mark consisting of a pictorial representation of the striped barrel. This mark was considered descriptive, and registration was refused.

A Philadelphia candy manufacturer applied for registration of the word "Fussy," as used in the phrase "A fussy package for fastidious folk." The Patent Office held that the word "Fussy," as used in the phrase, was merely a descriptive term —an adjective qualifying "package"—and registration was accordingly refused.

The word "Spearmint," being a descriptive word, was refused registration as a trade-mark for Wrigley's Spearmint chewing gum, but the representation of a spear was considered registrable.

Various applicants have sought registration for trade-marks which, while they are meaningless to English-speaking people, are really descriptive terms taken from foreign languages. Such words are not registrable, for the Patent Office makes no distinction between languages. The phrase "Lait de Violettes," meaning the French "Milk of Violets," was rejected as a mark for perfumery. "Elegancia," the Spanish equivalent of the English word "Elegant," was rejected as a mark for perfumery. A descriptive word in a language as little known as Esperanto is, nevertheless, unregistrable. "Saniga" means "Sanitary" in Esperanto, and it has been accordingly refused registration on the ground of being a descriptive term.

In considering the question of descriptive marks, the difference between description and suggestion should not be overlooked. Suggestiveness is a highly desirable quality in a trade-mark, and many excellent and legally valid marks are suggestive. The name "Hydegrade," a registered trade-mark, applied to a well-known fabric, is suggestive of high quality, but it is not descriptive. It is a coined word, composed of the elements "Hyde" (name of owner) and "Grade." Another example of an excellent suggestive mark is "Rubdry" applied to towels.

Pictorial marks are often highly suggestive without being descriptive. The Baker Chocolate girl, depicted in the act of serving a cup of cocoa, suggests daintiness, taste, beverage, quickness in serving, and refreshment.

The word "Ideal," used in connection with a fountain pen, is considered fanciful, and not descriptive. It would seem that a very fine distinction is made here, as this word is an ordinary descriptive word, commonly used to express a state of perfection, as in the expression "An ideal day." It may be said, on the other hand, that nothing ever reaches an ideal condition, and, in that sense, the mark may be considered fanciful.

Geographical names, like descriptive terms, are the common property of all who use the language. No one manufacturer can appropriate such a term for his own exclusive use as a trade-mark unless he uses it in an arbitrary or fanciful sense. The only exceptions to this principle are to be found in the case of manufacturers who have adopted geographical terms as their trade-marks and have used them so long, without opposition or protest, that they have acquired a common law right to their exclusive use.

Among the geographical marks rejected by the Patent Office are the following:

"Yale," applied to hosiery; "Cloverdale," for canned fruits and vegetables; "Red River Special," as a mark for agricultural implements; and "Aurora" on shoes—the name "Aurora" being applied to localities in at least twenty States of the Union.

It would seem in the light of common-sense, that in the last-named case (that of "Aurora") the ruling of the Patent Office is on a very narrow basis indeed. The word "Aurora" has no geographical significance to the average person. It calls up a mental image of the dawn. If this case, and some others like it, are considered valid precedents, every applicant for trade-mark registration must be prepared to submit his application to the stern criticism of the Post Office Directory, with its catalogue of fifty thousand or more names. (It is interesting to observe that, in a later case, the Patent Office allowed the registration of "Aurora" as a trade-mark for oils, lard, syrup and honey.—Aspegren & Co., ex parte, 100 Official Gazette, 684.)

"Tabasco" was refused registration as a mark for a sauce on the ground that it is a geographical term, Tabasco being the name of a State in Mexico. "French" was rejected as a trade-mark for paint. On the other hand, "Celtic" has been registered as a trade-mark for tea. The word "Celtic" has reference to a race, of which the Irish are only one branch. It is not applied to any particular country or section of the globe.

The map of the United States has been refused registration as a trade-mark for sugar. "American Lady" was refused registration on the ground that the word "American" is geographical. When a geographical term, applied to merchandise, is used in a fanciful or arbitrary sense—that is, when it conveys no deception in regard to the origin of the merchandise—it may be registered as a valid trade-mark.

"Dublin" is a valid trade-mark for soap, although the soap is made in America. In the case concerning this mark it was shown that it is the practice of soap manufacturers to call their products "Limerick," "Scotch," "Irish," etc., and that the buying public is aware of the fanciful use of these names and is not deceived thereby.

"Vienna," applied to bread, is considered valid. No one expects bread made in Vienna to be sold in America, consequently no one is deceived by this fanciful use of the word.

"Gibraltar" is registered as a trade-mark for belting. It is true that Gibraltar is a geographical name, but its suggestiveness in regard to belting conveys the mental picture of strength, rather than the idea of origin.

The student of trade-mark conditions, having learned how rigorously the Patent Office interprets the section of the law applying to the registration of geographical terms, will perhaps be puzzled by the number of trade-marks of this class which seem to be valid and well-established.

The explanation of that is that many geographical names, which could not have been protected *ab origine* as trade-marks, have acquired a secondary meaning by long and exclusive use by a particular manufacturer. Such marks fall within the protection of the common law.

Some of these common-law marks are registered under the ten years' clause. Among well-known geographical trade-marks may be mentioned "Bristol" applied to fishing-rods; "Kalamazoo" applied to stoves; "Manhattan," the name of a brand of shirts; and "Elgin," "Waltham" and "Illinois," the names of watches.

(*To be continued.*)

Notes for Inventors

A Coat and Suspended Trousers.—Patent No. 1,031,719 to G. A. Kurz of Zanesville and H. C. Shonting of Columbus, O., discloses a coat with trouser legs supported from within the coat, and straps which are detachably secured to the upper ends of the trousers legs.

Preserving Oil Paintings by Nitrogen Gas.—In patent No. 1,031,727 Karl Mussbeck of Munich, Germany, has a means for preserving oil paintings, provides a casing for the painting having a glass plate to inclose the painting which casing is air-tight and supplies a charge of nitrogen gas within the casing.

An Abrasive Bowl that Pares Vegetables.—This vegetable peeler patented to Henry Robinson of South Orange, N. J., No. 1,031,735, includes a bowl-like receptacle which is rotated upon a vertical axis and has its inner side walls provided with an abrading surface which when revolved or moved in contact with the vegetable operates to remove the skin therefrom.

Storing and Launching Lifeboats.—A number of lifeboats are nested one in the other and carried from the ends of swinging davits by independent hoisting ropes and blocks so the lifeboat can be launched successively from the same davits from which they are suspended. The patent, No. 1,033,480, was issued to Henry A. Seymour of Washington, D. C.

A Novel Pneumatic Tire.—James P. Clare of Stratham, New Hampshire, has secured a patent, No. 1,033,229, for an inflatable tire which comprehends two separate tubes combined to form the tire. The two separate tubes are united to form a tire body and are so arranged and united that each separate tube will form a separate compartment, and portions of the combined tubes will form a third compartment.

Making the Kettle Shut Off the Heat.—Knud Valdemar Rotzov of Malmo, Sweden, has patented, No. 1,031,874, a device for controlling the heat by the steam from the liquid being boiled. In doing this he provides a cooking apparatus with a heating producing medium in the form of gas and a valve for regulating the supply of gas. The heat causes liquid to boil and the steam from the liquid being boiled by its condensation, operates upon the regulator for controlling the supply of gas.

A Novel Core for Elastic Tires.—William Barbour of Glasgow, Scotland, makes an elastic or resilient body as a filler for cushion tires and the like which comprises an inner member or body formed from the depilated hides of animals in a moist condition and an outer member inclosing said inner member and of water-proof material so it will conserve the moisture of the inner member, the depilated hides being wound under tension. Patent No. 1,031,671 has been issued to Mr Barbour for the invention.

A Bill to Authorize the War Department to Test Upon Ships a Device for Hoisting and Lowering Lifeboats at Sea.—Mr. Peters has introduced in the House of Representatives a bill authorizing the Secretary of War to construct and test upon one or more army transports or other ships in the War Department, the device for hoisting and lowering lifeboats at sea devised by A. S. Eells of Boston, Mass., and to meet the expenses out of any money in the treasury not otherwise appropriated.

A George Westinghouse Turbine.—In patent No. 1,031,757, George Westinghouse of Pittsburgh, shows a re-entrant turbine which has a bladed rotor element with a fluid discharging device which is movable toward and from the rotor and a stop on the turbine stator is arranged to limit the movement of the fluid discharge device toward the rotor. In the same issue Mr. Westinghouse patents, No. 1,031,759, a vehicle supporting device in which pneumatic cylinders are pivotally supported in connecting yokes and are interposed between the yokes and the axle of the vehicle forming stress transmitting devices.

Versatility of Women Inventors.—Women have not only patented cooking utensils and other household appliances, but many inventions along other lines have been made by them, as the records show that they have secured patents for cultivator attachments, baling presses, dump wagons, vehicle brakes, barrel taps, window frame and sash, calendar clocks and electric clocks, watch makers calipers, numerous educational appliances, heating apparatus, gas making apparatus, electro medical appliances, horseshoes, motors and wind mills, plumbing devices, railway appliances, theatrical apparatus and in numerous other mechanical fields.

Legal Notes

Recent Adjudicated Patents.—Out of nine adjudicated patents reported in the *Patent Office Gazette* of July 9th, 1912, only one was held void. In the other eight cases, two patents were held valid and infringed and in five cases no infringement was found.

A Door in an Interference Proceeding.—In an interference case of Summers v. Clark involving priority of invention of a door arrangement for dump cars, in which the doors at the bottom of the car roll open laterally of the car to discharge the load, the Court of Appeals of the District of Columbia in reversing the decision of the Commissioner of Patents, and awarding judgment to Summers, said it was constrained to believe with the Examiner of Interferences and the Examiner in Chief that Clark is not an independent, original inventor of the subject-matter in question.

RECENTLY PATENTED INVENTIONS

These columns are open to all patentees The notices are inserted by special arrangement with the inventors. Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN

Electrical Devices.

TELEPHONE ATTACHMENT —J E ROSS, care of General Delivery, Cleveland, Ohio. The object here is to provide an attachment having an ear tube with members connecting the ear tube with clamping members, which embrace the conical portion of a telephone receiver, to press the cushion member mounted on the ear tube against the head of the receiver, around the opening of the said head.

Of Interest to Farmers.

INCUBATOR. —C. J. DITTBRENNER, P. O. Box 176, Cornwall, N. Y This incubator can be readily assembled and disassembled, and is arranged to insure a uniform heating of the eggs in the hatching compartment, to provide a proper circulation of air, to moisten the air, and to furnish a suitable running space or nursery for the hatched chicks

COW STABLE- J. A MONTGOMERY, Walton, N Y, deceased, Harriet I Montgomery, W H Montgomery, and M. C Montgomery, administrators This invention provides a stable where the atmosphere infolding the head and breathed by the cow is maintained separated from the atmosphere infolding the body of the cows, provides a flexible neck confining partition to be placed to permit the animal assuming various positions standing or recumbent; provides sanitary and inspection means and suitable ventilation augmenting devices for the head confining section of the stable.

Of General Interest.

SAFE DOOR.—G COOK, care of Dr R S Elliott, Laona, Wis The inventor provides means especially adapted for safes having circular doors, for receiving explosives introduced between the door and the safe, and through the openings of the lock and bolt operating means, and conducting the explosives away from the door, there to be exploded, or otherwise disposed of

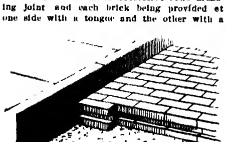
OILING ATTACHMENT FOR STREET SPRINKLERS —R E CARLTON and S Y CULLEY, Latonia Station, Covington, Ky This invention is an improvement in the application of oil to the surfaces of streets or roadways, which is desirable as is well known for the laying of dust as well as for the hardening of the road By the improvement oil is supplied at the same time the surface is sprinkled with water

BENCH —H A WHEELER and C W. WHEELER, Eddyville, Neb The principal object of the invention is to provide a convertible bench adapted to a variety of uses, particularly the needs of osteopathy and chiropractics, the construction and arrangement being such that the parts are movable relatively one to the other, whereby the outfit is capable of manifold application.

BAG HOLDER —L. A DYKEMAN, Maryland, Otsego Co, N Y This improved form of bag holder is especially adapted for use on counters An object of the invention is to provide a holder which is adapted to contain a number of pockets of varying sizes whereby bags of varying capacities may be held in convenient position for use.

RECEPTACLE —W J HAMILTON, care of Park Hotel, Franklin, Pa This invention relates to receptacles, and more particularly to barrels, and the purpose is to provide one with a plurality of side members having flanges which are engaged by sleeves for holding the side members together and against the heads which are disposed to cross in the side members

BRICK PAVEMENT —C. C PETTIT, Greenford, Ohio For the purpose of securing interlocking of adjacent rows of bricks to prevent displacement, shifting or sagging of a pavement at any one point over uneven or faulty foundation, use is made of interlocking rows of bricks, the bricks in successive rows breaking joint and each brick being provided at one side with a tongue and the other with a



INTERLOCKING BRICK FOR PAVEMENTS.

groove, both extending from one end of the brick to the other end thereof, and the tongues of the bricks in one row fitting into grooves of adjacent joint-breaking bricks in the next row, so that each brick in each row is sustained The engraving pictures a perspective view of the pavement

FILM CAMERA.—H. W HALES, Ridgewood, N. J. The main object here is to allow not only pictures of different sizes to be taken on the same roll of film at will, but to economize on the cost of operation by securing more exposures from the same roll or film, or if the usual number, then of a greater length than originally intended.

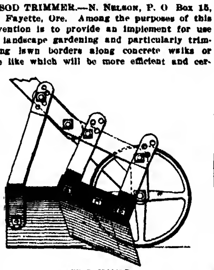
SAFETY RECEPTACLE —W. WINKELMANN, 494 12th St., Brooklyn N Y Bottles containing milk or other merchandise may be deposited in this receptacle, so as to prevent the latter from being tampered with by unscrupulous persons when the vender leaves

SAFETY RECEPTACLE.

them outside of the buildings. This simple inexpensive and perfectly secure device is normally maintained unlocked, but it may be automatically locked or placed in a receptive locking condition by the insertion therein of a full milk bottle or other merchandise. The accompanying illustration presents a vertical section of the receptacle showing it locked

Hardware and Tools.

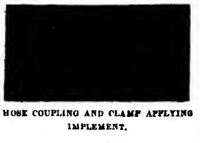
SOD TRIMMER.—N. NELSON, P. O Box 15, La Fayette, Ore. Among the purposes of this invention is to provide an implement for use in landscape gardening and particularly trimming lawn borders along concrete walks or the like which will be more efficient and cer-



SOD TRIMMER.

tain of operation than those usually employed, and that, too, with a minimum expenditure of power The adjustment of the mold board is intended to accommodate operators of different heights, and this adjustment may be made independently of the adjustments of the cutter, the board being adapted to swing on the pivot according to such adjustments. The engraving gives a clear exposition of the trimmer in operative position

HOSE COUPLING AND CLAMP APPLYING IMPLEMENT —WM TANKERSLEY, La Junta Colo This patent, No. 994,664, consists of certain novel features which meets with enthusiastic reception by water, air and steam users, as it is adapted to the various



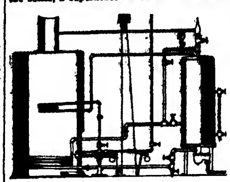
HOSE COUPLING AND CLAMP APPLYING IMPLEMENT.

sizes of fittings and makes of clamps, which are provided with two rings for various means. A spud for holding the fittings with an adjustable pin in gripping terminal, a slidable frame provided with a thumb screw for a clamping device, make it applicable to any place.

Heating and Lighting.

BURNER —J O BROOKBANK, Driftwood, Pa. This invention provides a burner for burning kerosene, coal oil, petroleum, gasoline or other liquid fuel, and is arranged to permit of conveniently and quickly starting the burner, to prevent overflow of the liquid fuel in the burner and to prevent the escape of obnoxious fumes or odors into the room where the burner is located.

OIL BURNING SYSTEM.—F. J. KARSEN, 420 Peavine St, Reno, Nevada For the purpose of this invention, use is made of a boiler connected with a source of water supply, and with the steam generator arranged in the shell of a heating apparatus separate from the boiler, a superheater in the said shell above



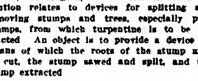
OIL BURNING SYSTEM.

the said steam generator and connected with the steam compartment of the boiler and with the burner proper located in the shell adjacent the steam generator, the burner proper being connected with a source of oil supply. The illustration herewith represents a side elevation of the system, parts being shown in section.

STOVEPIPE RETAINER.—W. H. PLEASANTS, Green River, Utah. This improvement provides a retainer to hold in operative position a stovepipe section to prevent the same from shifting in the stovepipe hole in the flue; provides a means for preventing the loosening of the holding devices therefor; and provides anchorage means to support other and connecting sections of the pipe.

Machines and Mechanical Devices.

GRINDING MACHINE.—G. W. HOADLEY, Garden Grove, Iowa The principal object of this invention is to provide a new and improved grinding machine made up of parts which are so arranged that the grinding wheel may be adjusted to different bevels and angles when it is desired to sharpen the sickle of a mowing machine, the construction and ar-



GRINDING MACHINE FOR MOWING MACHINES, ETC.

rangement of parts being such that the device may also be used for grinding chisels, axes, and the like. The device is also adapted to be held in such a position that it may be used as in the ordinary grinding wheel. The view pictures the device in use in grinding a mowing machine sickle.

MACHING FOR SPLITTING AND REMOVING STUMPS —A. S HUNTER, SR., 222 3d St., N. W., Washington, D C Mr. Hunter's invention relates to devices for splitting and removing stumps and trees, especially pine stumps, from which turpentine is to be extracted An object is to provide a device by means of which the roots of the stump may be cut, the stump sawed and split, and the stump extracted

BUTTON GRINDING MACHINE —W. HERZOG, 9 Prospect St, Garfield, N. J. This invention has for its particular object the forming of perfect buttons from "seconds" by means of a machine of simple construction containing relatively few parts, which is adapted to form buttons of different shapes and sizes.

PUMP.—G G. MCNEE, Box 442, Helper, Utah The inventor provides a pump more especially designed for irrigation and similar work, and provided with one, two, or more pairs of cylinders to permit of pumping a large amount of water in a comparatively short time, and without requiring much motive power for actuating the pump.

EXCAVATOR.—N. A. LYBECK, 1 Madison Ave., Room 6060, New York, N. Y. The employment of this invention is particularly designed for the construction of canals and for the maintenance of waterways, by permitting the same from being filled or impeded by sedimentary deposit or débris. An incidental purpose is to economize in the cost of the operation of constructing the canal and of maintaining the clearway of the stream.

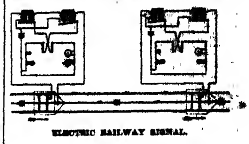
Prime Movers and Their Accessories.

GASOLENE FILTER.—F. CATCHPOLE, Pagosa Springs, Colo The device is intended more particularly for use in connection with the gasolene inlet of carbureters of gas engines. The inventors provide a water chamber below the gasolene chamber for receiving any water in the gasolene, and a filtering dome is arranged around the inner end of the gasolene inlet pipe. Below the filter dome is an adjustable guard which regulates the communicating space between the gasolene and water chambers, and prevents splashing of the water on the filter. It is especially for use with automobiles.

Railways and Their Accessories.

SIGNAL INDICATING DEVICE FOR RAILWAYS.—E. DEBRIE, 12 Rue des Capucines, Paris, France. This invention has for its object a signal indicating device for railways, and [illegible] the transmission of the [illegible] to the engine-driver, while [illegible] which causes the automatic [illegible] of the railway trains.

ELECTRIC RAILWAY [illegible] KISTLER, P. O. Box [illegible] [illegible] This invention refers to improvements in railway signals, and a particular feature of it is shown in a diagrammatic view of the arrangement of the signaling circuit when two trains are proceeding in the same direction. An object



ELECTRIC RAILWAY SIGNAL.

is to provide a device by means of which two engines which are approaching each other may be warned by means of signals to indicate such approach, when these engines are approaching head on, or when both are going in the same direction. Further, to provide means for indicating whether an engine is approaching from ahead or from the rear.

RAILWAY SWITCH.—A. COULOMBE, 91 Bullard St., New Bedford, Mass. In the present patent the invention relates to railway switches, and the object is the provision of a switch having a rock shaft extending longitudinally of the main tracks, with two arms

RAILWAY SWITCH.

secured to the rock shaft, one of the arms having means for operating the switch rail, and the other arm having means by which it is adapted to be operated by an adjustable member on a car. The accompanying illustration pictures the invention in a plan view.

Pertaining to Vehicles.

VEHICLE WHEEL.—V. SANFRY, Box 123, South Bend, Wash. This invention relates to an improvement in wheels, and particularly to resilient wheels, and has for an object the construction and arrangement of improved means which will present a wheel structure adapted to resiliently give when the wheel is in use.

WIND SHIELD FOR AUTOMOBILES.—W. A. PEARSON, Troy, Ohio. This inventor provides a shield having hinge members, which are held yieldingly relatively to each other by springs, so that the members of the wind shield may be disposed in a plurality of positions relatively to each other, and be supported relatively to the hinge members.

AUTOMOBILE DRIVING GEAR.—J. HETTRICH, P. O. Box 664, Lincoln, Neb. The purpose here is to provide a direct driving connection between the motor and the wheels, so connected that there will be no interference with the steering mechanism, and wherein the differential connection of the wheels is independent of the axles.

VEHICLE WHEEL.—J. W. CALTA, Platte, S. D An object here is to provide a device to take the place of a wheel provided with a pneumatic tire. This device has all of the advantages of the pneumatic tire, but is not as costly as the latter. Further, the object is to provide a wheel having a combined spring and pneumatic action, which results in a wheel having admirable riding qualities.

NOTE.—Copies of any of these patents will be furnished by the SCIENTIFIC AMERICAN for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

Notes and Queries

Kindly keep your queries on separate sheets of paper when corresponding about such matters as patents, subscriptions, books, etc. This will greatly facilitate answering your questions, as in many cases they have to be referred to experts. The full name and address should be given on every sheet. No attention will be paid to unsigned queries. Full hints to correspondents are printed from time to time and will be mailed on request.

(12669) R. T. asks: Could you name a substance that would stop completely the attractive action of a magnet? A. There is no material known which can stop completely the attractive action of a magnet. Magnetism passes through everything with considerable ease. Through iron and steel it passes with much greater ease than through the air and other common things. For this reason you can surround a magnet with a heavy casing of soft iron, and the magnetic lines will go around the magnet in the iron instead of leaving the iron and passing through the air inside the shield. This is the nearest to a magnetic shield that can be had.

(12670) A. H. W. says: Which is the better non-conductor of heat, fine wool or a space of equal area and depth filled only with air? If an attempt is made to use a chamber of air as a non-conductor, would it be necessary to make the chamber entirely "air tight?"—that is, altogether proof against egress and ingress of outside air. If an air chamber is used as a non-conductor, is it necessary that the inclosed air be below the temperature of the outside air? A. Heat always flows from bodies of higher temperature to adjacent bodies of lower temperature. "Non-conducting" materials are properly only slow-conducting, since all substances transmit heat in some degree. Dry gases, such as air, are very bad conductors; but if free to circulate in a hollow wall, the molecules of the air carry the heat rapidly by "convection" as they move about the space. For good effect, as heat insulation, air must be confined in cellular spaces, the smaller the better. All effective insulators, as wool or cork, depend for their action on the fact that they entrap large quantities of air in small spaces, so that it cannot circulate readily and transfer heat through the thickness of the insulating wall. It is, therefore, evident that the air should be confined closely, and that it will always be warmer than the cold side of the wall and colder than the warm side.

(12671) E. L. writes: Your favor of July 1st is very disappointing; it brings me up against a stone wall and does not tell me why I cannot climb over it. "An electric motor cannot charge a storage battery." Why not? If you can tell me of any publication that will answer that question, I will take it as a great favor. Funk & Wagnall's Encyclopedia: "Shunt machines are the most suitable for charging storage batteries; . . . the same machine which converts mechanical into electrical energy will serve the opposite function equally well. So I thought, by using one or more switches, the battery might be connected to the electromagnet or switched off to the armature as it was wanted to charge the batteries or to be run as a motor. A. The reason why an electric motor cannot charge a storage battery is that a motor is not a generator of an electric current. It receives electric current from some other source and transforms it into mechanical energy. A motor is often, as you know, capable of being used as a dynamo by applying steam or other power to it to turn the armature. It is then a dynamo and not a motor. All motors cannot be used in this way. Whether your motor can be, may be easily determined by an inspection by an electric engineer, say the engineer of the lighting station in your city. If feasible, you may then provide a gas or other engine for it, or even a small dynamo, which may be driven by your motor and be so wound as to furnish just the current required by your battery. Then, too, there are ways of cutting down the current to the capacity of your battery, and connecting it directly to the line which runs the motor. This mode is likely to be more expensive than to buy a small dynamo and run it with your motor. The statement you quote, "The same machine which converts mechanical into electrical energy will serve the opposite function equally well," is not always true. Many motors cannot be used as dynamos without alterations. No motor can be made a dynamo by simply the turn of a switch. A motor can be made a dynamo only by driving it with external power. A dynamo always transforms mechanical into electrical energy. You will find a much more correct statement of the interchangeability of dynamos and motors in Sloane's "Handy Book of Electricity," which we send for $3.50, as follows: "Electric motors had been constructed for many years before it was definitely decided that the same machine could receive electric energy and convert it into mechanical energy, thus constituting itself a motor, or could be operated by a steam engine, water turbine, or other prime motor, receive mechanical energy, and convert it into electric energy. It then is a generator or dynamo." (Page [illegible].) We hope this statement of your [illegible] is plainer than our first. We simply gave the answer without explanation in the haste of a [illegible] day, but are pleased to amplify it.

NEW BOOKS, ETC.

AN UNSINKABLE "TITANIC"; EVERY SHIP ITS OWN LIFEBOAT. By J. Bernard Walker, Editor of the SCIENTIFIC AMERICAN. New York: Dodd, Mead & Co., 1912. Size, 5¼ x 7¾; 185 pp.; 40 illustrations. Price, $1 net.

The object of this work is to show that during the past fifty years of progress the shipbuilder has been so much occupied in developing the speed and luxury of ocean travel that he has neglected to make the ocean liner reasonably safe. The most startling feature of the loss of the "Titanic" was the fact that she went to the bottom so soon after the collision. Both the owners and the public at large believed that the great ship was practically unsinkable; yet in the brief space of two and a half hours after striking, the "Titanic" sank in 2,000 fathoms. The most important lesson of the disaster is not the need for more lifeboat provision or for more careful navigation, though both are necessary. Reforms should begin with the ship itself, which should be so constructed that in the event even of such a serious collision as that of April 14th, a ship will serve as its own lifeboat, and remain afloat until the rescuing vessels, summoned by wireless, can come to its aid and transfer the passengers.

That such ships can be built is clearly proved by the fact that the first large ocean liner, the "Great Eastern," built over half a century ago, was so carefully safeguarded against sinking that, after running over a submerged rock off Montauk Point, and receiving far more serious damage to her hull than the "Titanic," she came safely to New York under her own steam. It is the object of this work to show that since her day there has been a steady decline in the art of unsinkable construction, and the book is a plea for a return to the principles of subdivision that were embodied in that fine vessel. This is the first time that a book has been written upon this vital subject of the safe construction of ships; and the argument for a reform in present methods and a return to the safe constructions of an earlier day is irresistible. The most vital chapter is one entitled "Safety Lies in Subdivision," in which, by means of diagrams, the various protective devices, such as bulkheads, watertight decks, and double skins, are clearly explained. The chapter on the "Great Eastern" contains a full description of that epoch-making vessel, with drawings and photographs showing her construction, and her appearance as she lay at the foot of Canal Street, New York. It is significant that the changes in ship construction suggested by the author are identical with those proposed, both by the Senate Investigating Committee and by Lord Mersey of the Board of Trade Investigation. In every chapter of the book will be found answers to the hundred-and-one questions which have been asked about this stupendous tragedy; and the author makes it perfectly plain just why this noble ship was lost, and how the recurrence of such a disaster may be rendered impossible.

The half-tones and drawings are admirably executed, the book is ably written, and the interest is sustained throughout. Readers of the SCIENTIFIC AMERICAN need no introductory to the author and to his clear and interesting mode of expression. Mr. Walker is an acknowledged authority on marine and naval matters, and yet his treatment of technical subjects is such as to appeal to laymen as well as engineers. As an excellent example of his readable and entertaining style, we need but point to the series of articles on target practice, which appeared in the SCIENTIFIC AMERICAN last fall, under the title of "The Log of a Landsman Aboard the Battleship North Dakota."

THE ART OF THE BERLIN GALLERIES. By David C. Preyer, A. M. Boston: L. C. Page & Co., 1912. Large 12mo.; 324 pp.; illustrated with full-page plates in duogravure. Price, $2 net.

Mr. Preyer's new volume concerns itself chiefly with the collection of the Kaiser Friedrich Museum, with a much briefer description of the nineteenth century paintings of the Royal National Gallery. The method followed in regard to the Kaiser Friedrich has been to give the Italian, Spanish, French, English, German, and Dutch-Flemish schools each a section of critical description, illustrated by fair reproductions of the more noteworthy canvases. The museum, while boasting comparatively few masterpieces by famous names, possesses such a broad, comprehensive stretch of work typical of schools and periods that its lessons are of the highest educational value. The Royal National Gallery, founded upon the 262 canvases bequeathed King Wilhelm by G. H. W. Wagener, has grown to 1,100 paintings, 333 sculptures, and 30,000 drawings and water colors, mostly by German artists. Among the mentionable plates of this section are the pleasing "Springtime in Ehringsdorf" by Karl Buchholz, the "Spring Day" of Böcklin, and the portrait of Mommsen by Franz von Lenbach.

THE GASOLINE AUTOMOBILE. Its Design and Construction. Vol. I. The Gasoline Motor. By P. M. Heldt. New York: The Horseless Age Company, 1911. 8vo.; 508 pp.; illustrated. Price, $4.

Mr. Heldt, prepared and fortified by eleven years' experience as editor of *The Horseless Age*, has given us an impressive work on automobile engineering. The first volume covers with much thoroughness all the elements, parts, and principles of the gasoline motor—the media through which it works, the laws of gases, the cycles, the conversion of reciprocating into rotary motion, the balancing of engines, and the oiling and cooling systems. Each important part of the motor is treated in a separate chapter, with profuse diagrams and succinct description. Motor testing, with the necessary indicators and apparatus, is also given a full and well-written explanation, and the resultant diagrams are shown, demonstrating out-of-phase crank motion, pre-ignition, late ignition, and slow combustion of ignited charge. In addition to photographic views of five modern motor equipments, a pocket in the back cover contains a book of valuable plates showing sectional diagrams of twenty standard makes of automobile engine. Mr. Heldt's volume is perhaps as well entitled to the adjective "exhaustive" as any other American work on the subject.

CHILE AND HER PEOPLE OF TO-DAY. An Account of the Customs, Characteristics, Amusements, History, and Advancement of the Chileans, and the Development and Resources of Their Country. By Nevin O. Winter. Boston: L. C. Page & Co., 1912. 8vo.; 411 pp.; illustrated. Price, $3.

Chile, the foremost maritime country of South America, well repays a thoughtful study and forces some optimistic prophecies of a greater future. With an extensive seacoast indented by splendid harbors, with mild climate, broad, fertile valleys, fine grazing grounds, and vast mineral wealth, it is physically favored beyond its sister nations. The strain of Araucanian blood gives to the national character a free, proud independence and a soldierly efficiency that must eventually combine with the natural resources to place Chile in a commanding position both on land and sea. By map, illustration, and sympathetic yet keen-visioned description, Mr. Winter places before us a vivid conception of Chile and her people, their activities, customs, aspirations, and present achievements. Among the appendices are some suggestions for travelers that, although brief, will conduce to the comfort and convenience of intending visitors.

GOD AND DEMOCRACY. By Frank Crane. Chicago: Forbes & Co., 1912. 16mo.; 72 pp. Price, 50 cents.

Whatever else they may lack one may always find in Mr. Crane's little preachments the vitality of optimism. He himself defines the scope and the limitations of "God and Democracy" when he says it is not a book of exhaustive argument, but of pointed suggestion. The dissertation seeks to show, in a reverent manner, how the idea of Democracy is altering our idea of God. The modern conception of God is less that of the Universal Ruler, and more that of the Universal Servant. Service is exalted above rule, and service, the writer believes, is for the first time in history acquiring a proper appreciation. "The greatest thing in the world is to serve."

THE CORONA COOK BOOK. A Collection of Choice Recipes with an Expansible Device for Keeping Personal Cooking Rules. By Ruth Alden. Chicago: The Abbey Company, 1911. Price, $1.25.

Strictly speaking, this is not a book at all, but a little box cunningly made to imitate a book, and containing recipes on separate cards, the subjects being self-indexing after the approved modern card-index system. Extra cards are provided, on which new or favorite recipes may be copied or pasted. Altogether it is a most convenient way in which to keep the recipes most frequently referred to, as any card may be taken from the box for ready use, and returned after its directions have been followed. The dishes furnished with the outfit are economical and nutritious combinations of plain and wholesome ingredients.

CRIMINAL PSYCHOLOGY. A Manual for Judges, Practitioners, and Students. By Hans Gross, J. U. D. With illustrations. Boston: Little, Brown & Co., 1911. 8vo.; 514 pp.

Hans Gross is probably the foremost criminal psychologist in Germany. He has had the practical experience of a criminal lawyer and a criminal judge in writing a book which is a marvel of erudition. The volume before us is a remarkable effort to produce what may be called a pyschological system which can be practically applied hy criminal judges and lawyers. The deposition of witnesses, perception, superstition, probability, illusions, lying, mistakes, and isolated influences—all of these are considered from a criminological standpoint. Crimes are of such complex nature as to demand the systematic diagnosis of the criminal. Heredity and environment, associations and standards, initiative and suggestive ability all play their part. The judge or the lawyer who knows nothing of psychology, and only his criminal law, must flounder about hopelessly when confronted with the complex issues in which these factors play their part. Who but a psychologist can distinguish between hallucination and lying; between a superstitious believer in the reality of an experience and one suffering from an actual hallucination? Whatever may be the opinion of lawyers and scientific men as to the value of scientific aid in administering judgment, Prof. Gross firmly believes in the value of criminal psychology. This work may be accepted as the most authoritative book of its kind. Indeed, it was the first really objective criminal psychology which dealt with the mental states of judges, experts, jury, witness, and criminals.

PRACTICAL CEMENT WORK. An Elementary Treatise on Cement Construction. By W. B. Henry. Atlanta, Ga.: The Concrete Age Publishing Company, 1911. 16mo.; 110 pp. Price, 50 cents.

"Practical Cement Work" is a little treatise which those newly interested in any form of this construction will welcome. It gives the simple fundamental principles of form building, waterproofing, coloring, and testing, tells how houses are built by this method, recites the processes of water and steam curing, and concludes with directions for making sidewalks, and floors for cellars, basements, and stables.

ASTRONOMY FOR ALL. By Bruno H. Bürgel. Translated from the German by Stella Bloch. London, New York, Toronto, and Melbourne: Cassell & Co., Ltd., 1911. Illustrated. 346 pp.

The author of this book, Bruno H. Bürgel, is a self-taught writer on astronomy and a pupil of the self-taught popular scientific writer, M. W. Meyer. Like his master, Bürgel has performed a useful work in emphasizing the more fascinating side of astronomy, and thereby awakening an interest in a science which cannot have too many devotees. His career is interesting. An eclipse of the moon, which occurred when he was thirteen years of age, aroused in him an undying interest in astronomy. His parents, however, were not in a position to gratify his desire for a university education. He was apprenticed to a cobbler and later to a printer, "where," he states, "I hope to get a chance to read much in order to educate myself." His first chance to study astronomy practically came when he received an insignificant post on the staff of *Urania*. Turning now to Bürgel's book, we find it written in a simple, sometimes even in a poetic vein. The chapter on Mars accepts the Lowell theory of the Martian canals, and even quotes with approval the statements of Flammarion and Klein, that Mars is inhabited. In the chapter of the sun, we find a little misinformation that ought to have been corrected. The sun motor in Pasadena, California, proved far less economical than the author states, and is now dismantled, we believe. Nothing is said of Hale's wonderful work with the spectro-heliograph. On the whole, for a good, popularly written book, this "astronomy" can be commended.

THE HELICOPTER FLYING-MACHINE. An Account of Previous Experiments, Including an Analysis of the Author's Turbine Machine, with Theory and Deductions. By J. Robertson Porter. London: "Aeronautics," 1911. 12mo.; 80 pp.; illustrated.

The ordinary types of direct-lift flying machines are characterized as efficient in weight lifting, but very unstable, and the main reason for this instability is charged to the fact that while one blade of the screw is advancing against a current of air, the opposite blade is at the same time traveling with the current, the resultant reaction of the blades thus failing to balance each other. To overcome this defect the author advocates the utilization of the turbine principle, in which the air set in motion by the rotating blades is directed downward by fixed deflecting surfaces, the pressure against the top fixed surfaces accomplishing the lift. Much of the work is merely speculative, and the experiments are shop tests made under not the best of conditions, but the determination of efficient curves, and some of the other formulæ and suggestions, should prove useful to experimenters in, and designers of, helicopter machines.

MODERN AMERICAN TELEPHONY. Edited by Arthur Bessy Smith. Chicago: Frederick J. Drake & Co., 1911. 12mo.; 790 pp.; illustrated. Price, $2.

The purpose of the manual is to help all whose duties call them into relationship with the theory, science, and art of telephony. After some preliminary explanation of the theories of sound and of induction, and of the application of principles in the transmission of spoken words, the reader is made familiar with the various circuits and systems, the battery equipments, magneto switchboards and switchboard installation, standard multiple switchboards, and testing apparatus. In the chapter on "Telephone Troubles and How to Find and Remedy Them," the difficulties most frequently encountered are cited, and all possible causes are given. Line and conduit construction, wireless telephony, and automatic switching are also made the subject of careful exposition.

STABILITY IN AVIATION. An Introduction to Dynamical Stability as Applied to the Motions of Aeroplanes. By G. H. Bryan. New York: The Macmillan Company. 192 pp. Price, $2.

Dr. Bryan attracted our attention by some striking contributions to *Nature* on the mathematical side of aerodynamics. The paper which he read before the British Association for the Advancement of Science aroused a very lively discussion, not all of which was favorable to Dr. Bryan. It is the general tendency to regard the flying machine as a shining example of an invention produced by practical men and not by scientists. There can be no doubt that the work done by the Wright brothers was far more scientific than most aviators are willing to acknowledge. At all events, even if the flying machine is the product of unmathematical reasoning, that is no reason why the aeronautical engineer of the future should not apply to his profession the same knowledge of mathematics which has come to be indispensable in other branches of engineering. It is the purpose of this volume to impart that knowledge so far as it affects problems of stability.

The Cream Separator

(Concluded from page 113.)

of Stockholm, Sweden, was one of the first inventors to confine himself to the development of the dairy separator. His inventions included mainly improvements in gearing, bearings, and shape of bowl. The company which worked his inventions early attained considerable success in the commercial field. It secured the ownership of the Houston and Thompson patent, and De Laval improved on it, and converted the raw idea into a practical machine. Ten years later, on the assignment to the company of the Bechtolsheim liner patents, the company secured an almost absolute monopoly in the manufacture of dairy separators.

Since the invention of the liner, progress has been steady and rapid At first the makers were so flooded by orders from creameries that they could not turn their attention to the improvement of the separator for other than creamery purposes The hand separator involved a number of problems not found in the power separator, but they were problems for the machine designer rather than for the inventor.

The hollow bowl separator is still in extensive use. For farm purposes, it possesses some striking advantages over the liner machine Its ease of operation and its few parts, making cleaning easy, commend it to many people. The modern hollow bowl is a long slender tube with a skimmer at the top. The liner separator, however, despite its defects, has the field. It is exclusive in the creameries Of the many farm separators on the American market, all but one are liner machines, and the majority of these belong to the disk type, described in detail in the original liner patent This consists of a number of dished steel plates spaced apart and secured to rotate with the bowl. The milk is fed rapidly outward and is separated between the disks. The central core is a hollow slotted tube which serves both to convey the milk and to support the liner plates. Besides the disk, there are a dozen or more other types of liners, and these are susceptible of an infinite number of modifications, many of which are in actual use. Much serious study is being spent in working out the mechanical adjustment of the most efficient liner possible Theoretical results are very difficult to demonstrate because even with perfectly transparent bowl and liner, it is difficult to determine the exact movement of the currents on account of their extreme rapidity of movement. Much of the work is being done by salaried experts in all of the larger factories, which have the equipment and funds necessary for carrying on the work.

The three problems of most importance are the problem of properly feeding the milk into the bowl, the regulation of the skimmer, and the cleaning problem. With or without the liner, the milk forms a hollow column in the rotating bowl. The richest cream is at the inner wall of the column, and the richness decreases toward the outer wall. Somewhere between center and circumference is the best point for applying the full milk. The direction of movement of the full milk on entering the bowl will manifestly have an effect on the efficiency of the machine The skimmer, too, is susceptible of improvement. Usually some form of hollow screw on an eccentric axis is used By turning the screw the richness of the cream can be regulated At present, however, there is no satisfactory way of making the adjustment while the machine is in motion The cleaning problem, while seeming to be simple, is in fact difficult and important. The bowl slush left in the separator contains much cheesy matter This is difficult to remove with cold water and impossible with hot water. In the presence of water, hot or cold, it acts much like eggs, and when the liner is a complicated one, the cleansing involves as much work as dish washing after a large meal. The slush is an excellent breeding place for undesirable germs, and unless the cleansing is thorough, the next charge of milk is liable to become badly tainted. This usually means a money loss to the farmer since creameries grade their cream and pay for it accordingly. So serious is this trouble that separator cream is seldom equal in flavor to hand skimmed cream. The solution of this problem would be worth a fortune.

When the farmer has six or more cows, and sells either cream or butter, the separator pays handsome dividends on the investment. The saving in cream alone over the older methods will do this. The whole milk can be separated immediately after being drawn, instead of waiting from twelve to twenty hours. The farm separator has also an advantage over the creamery separator. Instead of daily trips, it means one or two trips a week, or better still, the cream can be taken along when another errand takes the farmer to town. The skim milk, instead of being left at the creamery or coming back with possible contamination of disease germs from other herds, is fed to the stock while still warm, and in its best possible condition. The farm separator has come to stay because it is a money maker for the farmer, and properly handled, it should be an important factor in conserving the fertility of the soil.

One of the difficulties in the way of complete separation of milk is the affinity of the small particles of proteids and oil for one another. Prof. Babcock made use of the fact that the proteids can be digested and dissolved in sulphuric acid, thus leaving all particles of butter fat free in a medium for which the particles have little or no affinity. He designed a compact and portable centrifuge, and test tubes so graduated that the proper proportion of milk and sulphuric acid could be introduced. The percentage of butter fat is indicated on direct reading. The method, because it enables even the most unskilled worker to make reliable tests, has superseded the old cumbersome laboratory methods, and is now in almost universal use in all countries where dairying is carried on.

The Motor Contest at Winnipeg

(Concluded from page 113.)

economy test. This was taken advantage of by some competitors who held their engines to as low a power output in the two-hour test as was consistent with economy, and then, with the fuel penalty removed, ran at the highest possible horse-power in the half-hour test. There were no points given on output of power in comparison with piston displacement, hence in one or two cases engines which had made very creditable showings from the practical standpoint, failed to get proper recognition

In the plowing tests a field of 240 acres had been secured 12 miles from Winnipeg, and intermittent, happy-go-lucky train service enabled the competitors and visitors to reach the spot. The furrows were three fourths of a mile long, and each engine made a total of six miles, regardless of the number of plows pulled This consumed from two and a half to three hours of actual plowing for each engine in addition to stops and turns. The field was not as smooth and uniform as had been secured in previous contests, consequently the draft of plows varied considerably more than the actual differences in the plows would account for. On the whole, the draft was much heavier than in any previous contest, and it is interesting to compare the figures of close to 900 pounds per 14-inch plow, $3\frac{1}{2}$ inches deep, with the ordinary figure of 400 to 500 pounds for the same plow twice as deep in Illinois and Iowa

Recording dynamometers gave the average draft very accurately, and an observer accompanied each outfit to get accurate data on the time, stops, condition of engine, and any other points which had bearing on the performance of the outfit. Careful measurements were taken of the fuel and water consumed in relation to the horse-power developed and the acres plowed. The score card was so arranged as to encourage the development of as high a horse-power as possible, consistent with economy, but no maximum test on the drawbar was included. The drawbar horse-power developed, therefore, is probably nearer the economy load in most cases than the maximum. This was illustrated by the larger Rumely tractor, which was used again in the engine gang-plow competition. It developed only 34.4 tractive horse-power in the engine competition and 42 in the plow competition, pulling a larger number of plows then because there was no penalty for fuel consumption. Points were given for the number of acres plowed per hour in comparison with the horse-power developed in the economy brake test, and this was another element tending to keep the showing on the economy run down to as low a horse-power as would still give economical results.

Another factor which seemed hardly correct, was the scoring of the engines on the distance traveled, or acres plowed, without replenishing fuel and water. The scoring was done simply on the percentage of the tank capacity which was used, and did not consider that only in very few instances could any tractor exhaust its supply of water before running hot. In the case of a steam tractor a certain amount of water must be retained in order to keep the crown sheet covered, and in the case of practically every internal-combustion tractor, not more than 10 to 25 per cent of the total water capacity could be used without causing difficulty.

Following the engine competition was a rather elementary contest for engine gang plows. Instead of making short rounds which would require considerable turning, and give the plowman a real opportunity to show up his gang, only one round was plowed and that of the same length as in the engine competition. It was found afterward that a portion of the points in the score card would have to be omitted on this account. Five companies had entered plows, but only three competed. One withdrew early, and another at the last moment, after the decision to plow but one round had been announced. The Avery Company won in the above classes with their self-lift plow, the Rumely plow being second, and the gang made by the J. I. Case Plow Works (not identified with the J. I. Case Threshing Machine Company) third.

The competition drew the usual gallery of visitors of all classes, although the contest each year is becoming of greater interest to the technical men and less to the farmer. One of the latter exclaimed, when he saw the engines working on the plowing field, "Why, that's just the same as we do at home." To the engineer, however, these contests afford a great opportunity to uncover his own hand for the sake of seeing what progress is being made by his competitors. The competition brings the most prominent men of this stamp together, and at least once a year the progress of the industry is thoroughly reviewed. There is no question that indirectly the results have thus been of enormous value to the farmers of the world. There is a striking contrast between the easy certainty with which the tractors and plows now perform their tasks, and the scenes at the first few contests.

There is considerable agitation in favor of having a motor contest in the United States, but it is out of the question for the average manufacturer to spare his valuable men for more than one such occasion in each year. So long as Winnipeg, having the advantage, clings to her opportunity, just so long does it seem certain that once every year the eyes of the traction engine world will all be turned toward this magnificent city of the Northwest.

A Sahara Sea

(Concluded from page 114.)

of fertility except moisture; also that there exist plentiful underground streams and reservoirs. Now, if these crystal supplies were brought to the surface through hundreds of artesian wells and properly irrigated through the land, supplemented by artificial reservoirs to conserve the precious waters of the occasional rains, ample resources thus exist in the Sahara itself for bringing about future conditions of fertility such as have been

INQUIRY COLUMN

READ THIS COLUMN CAREFULLY. You will find inquiries for certain classes of articles numbered in consecutive order. If you manufacture these goods write us at once and we will send you the name and address of the party desiring the information. There is no charge for this service. *In every case it is necessary to give the number of the inquiry.* Where manufacturers do not respond promptly the inquiry *may* be repeated.

MUNN & CO., INC.

Inquiry No 9260. Want addresses of parties able to ship corundum, garnet, flint, emery or any material suitable as an abrasive.

Inquiry No. 9261. Wanted a manufacturer to make card games.

Inquiry No. 9262. Wanted to buy a glass which is a conductor of electricity, and the address of the makers of the same.

Inquiry No. 9263. Wanted name and address of manufacturer of pantaloon stretchers with clamps, which is capable of being folded up.

Inquiry No 9264. Wanted the name and address of manufacturers of date pitting machines.

Inquiry No. 9265. Wanted the names and addresses of manufacturers of machinery for making picket fences.

Inquiry No. 9266. Wanted to buy machinery for fastening wire cloth to wooden frames with coppered tacks.

Inquiry No. 9267. Wanted addresses of manufacturers of metal specialties in connection with plate or window glass.

Inquiry No. 9272. Wanted names and addresses of engravers and mounters of fine quality maps or plans of large cities. Large order.

Inquiry No. 9273. Wanted to buy a globe for a parlor fountain, working on the Heron system.

Inquiry No. 9274. Wanted the name of a manufacturer of a machine to make cushion covers for fruit crates.

Inquiry No. 9275. Wanted name and address of manufacturer of stock patterns of platen job printing presses.

Inquiry No. 9276. Wanted a household convenience and necessity which can be retailed at a profit at a price of from $1.00 to $2.00.

Inquiry No. 9277. Wanted a machine for packing dry batteries.

Inquiry No. 9278. Wanted a machine for separating crab meat from the shell.

Inquiry No. 9279. Wanted a machine for shredding asbestos board.

Inquiry No. 9280. Wanted names and addresses of manufacturers of machinery for stuffing dolls and teddy bears.

Inquiry No. 9281. Wanted to buy machinery for bleaching walnuts and ivory nuts.

Inquiry No. 9282. Wanted name and address of manufacturer of coin-controlled [illegible] for automobile use.

[illegible] in formerly arid regions of the [illegible] States.

Many schemes for irrigating the Sahara have been discussed. The old project, first broached by the French engineer, Col. Roudaire, and indorsed as entirely feasible by De Lesseps and other competent authorities, has never been utterly cast aside. To let in the waters of the Mediterranean to flood the most sunken portions of the Algerian Sahara and thus render fertile large tracts of otherwise barren sand" would not by any means change the whole desert into a vast inland sea, as so many people have imagined, nor in the least affect the climate of Europe, since only some 3,100 square miles of territory, in the form of two distinct lakes in central and southern Algeria, would be drenched.

Prof. Etchegoyen, however, wishes to construct a deeper and longer canal so as to flood a much more extensive tract of desert. But it should be remembered that, since by far the greater part of the Sahara is from seventy feet to more than a mile in elevation above ocean level, and those tracts which lie below ocean level are chiefly valleys between the hills and mountains or the basins of ancient lakes never very extended in area, a Sahara Sea would consist only of an exceedingly irregular body of water containing many islands and extending into the unflooded districts in a multitude of bays and coves. It would be considerably less than one third the size of the Mediterranean. The reported "one half" is somewhat exaggerated.

Now arise the various questions of what important effects such a sea would produce upon the earth. Without discussing further any political or economic influences, there is still much to consider with respect to its possible physical influences. At last, in the progress of human achievement, mankind fears the power of its own ingenuity.

The writer feels that this alarm can be happily allayed, so far as a Sahara Sea is concerned. We are warned that "by the displacement of so many billions of tons of water, the equilibrium of the earth would actually be affected." Let us figure it out. Suppose the Sahara Sea should have an entire area of 250,000 square miles (thus allowing generously for any doubtful regions of desert that might become flooded) and a mean depth of 200 feet. Since one square mile contains 27,878,400 square feet, this entire area would contain 6,969,600,000,000 square feet and 1,393,920,000,000,000 cubic feet. Division of this sum by 40 (the number of cubic feet displaced by one ton)—the result is 34,848,000,000,000 tons of water required to flood the Sahara as suggested. If the canal to admit this water were cut through the north coast of Africa, these thirty-five thousand billions of tons of water would flow in from the Mediterranean Sea, and at the same time the Atlantic waters would flow into the Mediterranean until a level was again established. If the canal were cut to the West African coast, water from the Atlantic would flow directly in, without visibly disturbing the Mediterranean. In either case, the process would be gradual; the flooding of the desert would not be a sudden, precipitous inundation.

Of course, 34,848,000,000,000 tons is a great deal of water. But compare its volume. In that little curve of the Atlantic Ocean which forms the coastline of the New England States and New Brunswick and part of Nova Scotia, there is an area just about equal to the product of 500 by 500, or 250,000 square miles—the same area allowed above for the Sahara Sea. There is a daily tidal rise in this locality varying from about ten feet along Cape Cod to sixty feet in some parts of the Bay of Fundy. Allowing a mean distribution of 20 feet rise, the number of tons of water thrown upon these shores twice every day is fully one tenth as many as would be required to form a Sahara Sea. No one ever fears that this tidal displacement of water will "unbalance" the earth, or in the language of science, disturb the obliquity of the ecliptic. Thirty-five thousand billion tons, in proportion to the bulk of the earth, is utterly infinitesimal. In proportion to the volume of the ocean it is as a drop out of a pailful. And it is proposed to spread out this slight burden of displaced weight over a region nearly at the equator. A little further reasoning, or experimenting with globes or balls, will show that, since the earth is not exactly spherical but is somewhat thickened at the equator and flattened at the poles, to disturb her present axis of 23½ degrees inclination it would be necessary to apply additional weight at either one of the two poles. Additional weight spread out at the equator could not affect the balance of the axis.

We are also warned that the climate of Europe would be endangered. That is a more interesting, because more plausible, objection. At present there is very little rain over the desert region of North Africa. Scientists agree that this dryness is due not to the arrangement of neighboring mountain ranges but to various physical causes in the region itself. Perhaps the presence of so extended a body of water might produce rains. Certainly it would equalize the temperature so that there would be less intense heat by day and less intense chill by night; but comparison with other regions bordering upon seas in the equatorial zone shows that it could not reduce the temperature of a tropical climate to that of any merely temperate region not influenced—as Bermuda is, for example—by warm winds or currents. That eliminates one of the assumed dangers. The warm climate of the British Isles is due to warm ocean currents which sweep their shores; it is most unlikely that drawing from the Atlantic Ocean the water required to form a Sahara Sea would deflect, to any serious degree, if at all, any of these great currents. That eliminates another danger. The third and last danger that has universal import consists in whether or not such a sea would too greatly cool the winds that blow from Africa across the Mediterranean to southern Europe. Paragraphs might be written in discussing this interesting point, in telling how the winds originate in this region, the direction and influence of the trade-winds, etc. But it is safe merely to predict that while colonists living upon the shores of the Sahara Sea would doubtless delight in any cool zephyrs that might blow from its surface around their homes, there would be no appreciable change in the "Afric breezes" that blow across the Mediterranean. Why, the Sahara Sea would be merely a big shallow pond, an unusually large irrigation reservoir, compared with the natural seas and great lakes of the world!

It should be remembered that if France reclaims the desert, she will do so for her own benefit. For several years Algeria has been to France what Florida is to New England during the winter months—her mainstay for all kinds of early vegetables. The green produce, leaving Algiers at noon, is unloaded at Marseilles in the afternoon of the next day, starts on the evening trains for Lyons and Paris, and within thirty-five to forty hours after leaving Africa is on sale in the Paris markets. It was this proximity that first attracted her attention to Africa. At the same time she is not likely to permit the carrying out of any scheme which could injure the climate of southern France and destroy the revenue of her noble vineyards.

The American Road Congress

MANUFACTURERS of road materials and machinery will have an opportunity to display their models before the very men they are most desirous of reaching at the American Road Congress, which is to be held on the Million Dollar Pier in Atlantic City, September 30th to October 5th. All the leading highway engineers of the States, counties, and cities have sent word that they will participate in the congress, and many of the States are making arrangements to have special booths at which full information may be obtained as to the development and the needs of each State.

Every type of road will receive thorough attention in the papers, and discussions beginning with the humble earth road and going through all the standard forms of construction, including the modern bituminous roads, brick roads, concrete roads, and all the forms of construction that are now in use.

Contractors who attend the congress will have an opportunity to see the exhibits of all manufacturers with whom they wish to do business, and to mingle with the public officials to whom they will look for contracts. They will hear some practical papers read by prominent contractors.

The Government exhibit, according to an announcement just made by Hon. Logan Waller Page, director of the United States Office of Public Roads and active president of the American Road Congress, will have a complete exhibit on the Million Dollar Pier, which will contain models of all the various types of roads.

The highway departments of all the States in the union will be represented at the Congress, and there will be a comparative analysis of the contract and force account system in road construction. Papers will also be read on the relation of the contractor to the public official.

The site chosen for the American Road Congress, which marks the consolidation of the convention interests of the American Association for Highway Improvement, with all its allied organizations; the American Automobile Association, with all its affiliated clubs and associations; and the National Association of Machinery and Material Manufacturers, will undoubtedly make a special appeal to the more than 100,000 officials employed throughout the country in supervising construction or maintenance of public highways. Many have written to the headquarters of the American Road Congress in the Colorado Building at Washington, to say that they intend to combine business with vacation by spending the week beginning September 30th at the sessions of the congress.

Automobile tours are being arranged by the American Automobile Association from all sections of the country, and many of the legislators and other officials of the various States intend to be present. The principal addresses will be made by President Taft and Gov. Woodrow Wilson of New Jersey.

Preserving Fresh Flowers

IN order to keep cut flowers from withering, the water which they lose by evaporation must be replaced. Hence the stems are placed in water, the absorption of which may be facilitated by cutting the end of the stem to a wedge shape and thus increasing the absorbent surface. The same effects are produced to a still greater degree by crushing with a hammer an inch or more of the stem.

After a time the wound becomes covered with products of decomposition, due to the presence of bacteria, which impede the absorption of water, especially if the air of the room is warm and the section is not sharply cut. It then becomes necessary to cut off the diseased part of the stem in order to lay bare the mouths of the capillary vessels.

According to *La Nature*, the life of cut flowers can be prolonged somewhat by substituting distilled water for river water. Hot water also gives good results, especially with fleshy plants like hyacinth and narcissus. When the flowers, kept in ordinary water, begin to fade, the bottom third of the stalk is immersed in very hot water. As the water cools the flowers resume their natural degree of stiffness. Before they are replaced in fresh water the portion which has been immersed in hot water should be cut off.

Various antiseptics are sometimes added to the water in which flowers are kept. The addition of a few pieces of wood charcoal retards putrefaction, but it is still necessary to change the water every five or six days.

Soap is employed as a preservative in the following manner: The flowers are first sprinkled lightly with fresh water

...are then placed in a vessel containing soapy water. Every morning they are taken out and completely immersed in pure water for two minutes. They are then sprinkled again and their stems are replaced in the soapy water, which should be changed every three days. It is asserted that flowers can be kept at least a month in this way. In another method the washings are omitted but the soapy water is changed daily. The solution is prepared, in quantity, by dissolving one ounce of white soap and one tenth ounce of common salt in one quart of water, and adding a little pulverized borax.

Sugar is also recommended as a preservative. The best results are obtained by dissolving in each quart of water about five ounces of sugar for pinks, three ounces for roses and six ounces for chrysanthemums. Good results have been obtained also with sodium carbonate (washing soda) and with ammonium chloride (sal ammoniac). The last named salt, however, alters the delicate tints of some roses.

In general, flowers which are to be kept long in water should be gathered early in the morning and in the state of buds about to open, and the stems should be immersed for two thirds of their length. In order to retard evaporation, the room in which the flowers are kept should be heated and ventilated as little as possible.

Evaporation can be prevented by covering the petals with a varnish made by dissolving 20 parts by weight of light copal, previously mixed with an equal weight of fine sand or pulverized glass, in 500 parts of ether. The flowers are dipped in this solution four or five times at intervals of ten minutes in order to allow the ether to evaporate. Flowers treated in this manner retain their freshness and beauty for a long time.

Finally, the following method is generally recommended for preserving flowers, and roses in particular, for long periods. A tin box is partly filled with very fine and perfectly dry salt (dried over a fire if necessary). The buds are laid on the bed of salt so that they do not touch each other, and the box is filled with salt and hermetically closed. If the dried buds are taken from the salt at any time within several months, and their stems are cut and placed in water, they gradually resume their original freshness and open.

A glass-stoppered jar filled with alternate layers of violets and salt, and kept at a moderate temperature, may be employed to perfume a room at any time after two weeks, and retains its fragrance many months, if not opened too frequently.

The Current Supplement

THE SUPPLEMENT, No. 1910, brings a number of good articles this week. Prof. Diaz-Ossa, of the University of Chili, is peculiarly qualified to speak to us on the manufacture of Chili Saltpeter. —The description of a recently installed museum devoted to animal life underground will interest our biological readers.—Dr. Steinmetz, famous for his work in electricity, addresses us this time on a question relating to another field of physics, and makes some very interesting reflections on the second law of thermodynamics.—The center-page article is devoted to the remarkable operations in damming the Mississippi for power purposes.—Our metallurgical readers will be interested in an article on the relations of iron, vanadium and carbon in steels.—A description is given of the low temperature laboratory at Leyden, in which Prof. Kamerling Onnes carried on some of his famous work.

Increasing the Visibility of Vapor.—In a patent, No. 1,031,250, Thomas A. De Vilbiss of Toledo, O., presents a method of demonstrating perfumes or toilet waters in which he mixes with the perfume or toilet water an odorless liquid of greater consistency, specifically glycerine, than the perfume, so that the visibility of the vapor produced is enhanced and the moisture of the vapor is retained, and then affects a [illegible]

Studebaker

The Car that Answers Your Every Demand

Is it Price? Studebaker cars are within the reach of even a modest income

Is it Value? Studebaker cars offer more value than double the price can buy elsewhere Equal in quality of material and workmanship to any car made

Is it Popularity? 75,000 Studebaker cars are already on the road and every owner is an enthusiastic booster

Is it Appearance? Note the just pride of every Studebaker owner in the style and good looks of his car

Is it Name? For over sixty years the Studebaker name has been a synonym for the highest mechanical skill and integrity

Is it Simplicity? Studebaker construction is so simple that any member of the family can run a Studebaker as well as an expert. Nothing to get out of order

Is it Comfort? Long easy riding springs, wide, deep seats, upholstering of the softest hand-buffed leather, the best curled hair over finest pillow springs explain the luxurious comfort of the Studebaker

Is it Guarantee? The Studebaker guarantee covers you for an entire year Any part that proves defective in that time is replaced free of charge.

Is it Prompt Delivery? Our enormously increased manufacturing facilities have now reached a point where we can promise prompt deliveries.

Is it Service? *Studebaker service is valid from California to Maine, and the nearest dealer is ready to make good. No writing to headquarters. No wait No argument*

A Battleship With Cruiser Speed

The Twelve-gun "Wyoming" Makes Over Twenty-two Knots

IMPROVEMENT in the motive power of ships, and particularly those of large size and power, has been as great in the boiler room as in the engine room—a fact which is too often overlooked. Not all the great *increase which has taken place in the speed of war-ships* during the past few years is to be attributed to the engines. The turbine, it is true, has done much, but superheated steam and the water-tube boiler have had a large share in the improvement.

Take the case of that handsome battleship, the "Wyoming," which recently, on its trial, made a speed of over twenty-two knots on one of its runs and an average speed of 21.828 knots for the four-hour run. The ship is driven by Parsons turbines, working on four propellers, and in the tests they gave the usual good results which we have come to expect from this very fine turbine. On the other hand, it would be simply impossible to supply the necessary amount of steam for the turbines from a battery of the old Scotch boilers. They would be too cumbersome and heavy, and space for a sufficient installation of them could not be found in the "Wyoming" without sacrificing some other necessary element in the ship. The boiler equipment consists of twelve B. and W. water-tube boilers, equipped with superheaters and all the latest requirements of up-to-date boiler practice. The total grate surface is 1,448 square feet, and the total heating surface is 64,234 square feet. The contract maximum horse-power, or in this case, "shaft" horse-power, is 28,000, which was exceeded.

It was only a comparatively few years ago that twenty-one to twenty-two knots was the standard speed for the cruiser. To-day, cruisers of from twenty-five to twenty-eight knots speed are becoming common, and battleships speeds are never less than twenty, and are sometimes as high as twenty-three knots.

The "Wyoming" is an enlarged "North Dakota;" and she embodies improvements which have been made as the results of the experience gained with that ship and her sister, the "Delaware," during the year or two that they have been in commission. The ship is five hundred and sixty-two feet in length over all, ninety-three feet two and one half inches in beam, and her mean draft is twenty-eight feet six inches. The full-load displacement is twenty-seven thousand, two hundred and forty-three tons. The contract speed was 20.5 knots, which she has, therefore, exceeded by nearly one knot. The displacement on trial was twenty-six thousand tons. The bunker capacity of the ship is 2,500 tons, but she also can carry four hundred tons of oil fuel.

The "Wyoming," and her sister, the "Arkansas," are the first battleships in our navy to mount twelve twelve-inch guns. The distribution of this battery is similar to that on the "North Dakota," but with an additional turret. It is mounted in six turrets, all on the center line. Two of these turrets are on the fore-castle deck, and the other four are on the main deck.

The arrangement of the turrets in three superposed pairs is symmetrical and adds greatly to the handsome appearance of these ships; in fact, we do not hesitate to pronounce them the most shapely super-dreadnoughts which are now under construction for any navy of the world.

The twelve-inch guns are of the new fifty-caliber type—a most handsome piece of great power, accuracy, and rapidity of fire. When it is fired with its maximum velocity of twenty-nine hundred and fifty feet per second the energy is 52,483 foot-tons. Because of erosion difficulties, it is not likely that this velocity will be used in actual service. Probably the service charge will give about 2,750 feet per second. The secondary battery consists of twenty-one five-inch, fifty-one caliber guns, so mounted that eleven guns are available on each broadside.

The armor plan shows a belt at the water line which is eleven inches at the top and nine inches at the bottom. Above this is another belt of armor fifteen feet deep and from ten to eight inches in thickness. The turrets and barbettes carry ten to twelve inches of armor.

The United States Navy may, in the future, build more powerful ships, but it can hardly produce a more handsome one than the "Wyoming."

Preventive Clinics in Industrial Establishments

THE only way to interest the manufacturer in the health of his employees is to prove to him that it pays in dollars and cents to improve factory conditions. When his profits are obviously affected, he is likely to be interested in the welfare of his employees, as a general rule. Some of the larger corporations, however, have reached a stage where they regard the health of their employees as they do their own, not from a mercenary point of view, but simply as a matter of fair play.

The whole matter is excellently considered by Dr. James A. Honeij in *The Engineering Magazine*, from which we quote the following paragraphs:

"Increased profit is represented by a more healthy, energetic attitude of the employee toward either his work or the purchasing public. If ventilation, temperature, and humidity are improved, and if an existing physical disturbance is corrected, physical action as well as mental activity must necessarily be greater. In piece work this is apparent. When the market demand is large, and space is limited, it is imperative that the individual piece worker not only be relied upon to produce a certain number of articles, but often he is urged to increase it. Does the atmospheric and physical condition have anything to do with the profits of the employer? Most decidedly.

"In general, then, we can demonstrate the economic basis for a preventive clinic. A case showing the importance of ventilation is cited by C. E. A. Winslow where the New England Telephone and Telegraph Company at Cambridge, Massachusetts, had installed a simple ventilating system in their operating room, in the spring of 1907. Dr. Winslow states the following in his report on the 'Cash Value of Factory Ventilation':

'The change in ventilation did not affect the attendance in the operating room during the summer of 1907. No direct effect could be expected at this season, since in warm weather, with windows open, natural ventilation of the room could scarcely be improved upon. During the winter of 1907-1908, however, a marked improvement was manifest. For the first three months of 1906 the average percentages of operators absent were 4.0, 5.6, and 4.1, respectively; for 1907 the figures were 5.2, 5.0, and 3.4, for 1908 they dropped to 1.8, 2.4, and 1.5. Comparing the three winter months only (January to March), it appears that 4.9 per cent of the force were absent in 1906, 4.5 per cent in 1907, and only 1.9 per cent in 1908. This means a net saving for the three months of 2.8 per cent of the force employed, corresponding to one and eight tenths the entire time of one operator.

'The original cost of installing the system of ventilation was in the neighborhood of $75. The saving in operator's time during the three winter months amounted to 23 working weeks, as indicated above (13 weeks × 1.8). Since the average pay of an operator is $8.50, this meant a saving of $195 to the employees in wages, and the increased efficiency due to the regularity of attendance paid good interest to the company.'"

Another case is cited in which the cost of installing a ventilating system was $6,000; the reduction of the percentage of absences due to illness was so great that the employer was compensated for his outlay; and while previously the employees were likely to become stupid in the latter part of the afternoon, the new system maintained alertness during the entire day.

Length, 562 feet; **beam**, 93 feet 2½ inches. **Mean draft**, 28 feet 6 inches. **Displacement**, 26,000 tons. **Full load displacement**, 27,243 tons. **Speed**, 21.3 knots. **Armament**: twelve 12-inch 50-caliber guns, twenty-one 51-caliber, 5-inch. **Armor**; belt 11 to 9 inches upper belt 10 to 8 inches; **turrets**, 12 inches. **Torpedoes**, two 21-inch, submerged.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

The Merchant Marine—Free Canal Fallacy

THE United States Senate by vote of eleven to forty-four has refused to strike from the Panama Canal bill the provision granting free passage through the canal to American ships. The correspondent of the *Times* at Washington is of the opinion that the overwhelming nature of the vote shows that there is no chance that further debate will change the matter before the bill is finally disposed of.

This action of the Senate means that it is the deliberate purpose of that body to violate the letter and, as many of us see it, the spirit of a most clearly-stated treaty obligation.

But it is not of the moral aspect of this question that we are about to write—we did that in our last issue. What we wish now to point out is that in exchange for this playing *fast* and loose with international obligations we are about to obtain a very doubtful compensation. The country is asked to believe that the remission of tolls to American ships using the canal, will prove to be a powerful and very effective agency in building up our defunct merchant marine. As a matter of fact, it will do nothing of the kind. So far as coastwise shipping is concerned, that is already protected; for the ships of *foreign* nations are prohibited from engaging in such trade. To remit tolls to coastwise shipping will be in effect merely to divert a certain portion of the profits of the canal from the National Treasury into that of the shipping companies that are benefited.

Equally short-sighted and fatuous is the belief that the remission of tolls will benefit our deep-sea shipping as a whole, and bring about a general revival of the American Merchant Marine. The causes which underlie the present moribund condition of our over sea trade lie too deep to be reached by any such expedient as the remission of canal tolls. The relief afforded would be too local and limited. Consider, for instance, our trade with South America. The remission of tolls to ships engaged in that trade would mean that those ships which run to South American ports on the west coast would receive the benefit of Government assistance, while those which run to ports on the eastern coast would receive no benefit whatever. On what practical grounds could such a discrimination be justified? Why should our trade to the western coast of South America, to Australasia, and to the Orient be so greatly assisted, and the trade to South American and European ports be left in its present hopeless condition?

The upbuilding of our merchant marine is one of the most complicated and difficult problems that ever confronted the Federal Government. The question should be considered upon broad and statesmanlike lines, and any stimulus that Congress may apply should be of a kind that will go to the very heart of the problem. The external application of a quack remedy (for such is this free-toll movement) will never do more than give a relief that is local and temporary. Our deep-sea shipping as a whole will remain in its present comatose condition.

The gain will be slight. The cost in loss of international prestige and reputation for square dealing (and as a people we have always prided ourselves upon that) will be appalling!

We note that one of the amendments to the bill calls for the admission to American registry of foreign-built ships exclusively owned by Americans. We are not prepared to admit that such admission would be altogether a benefit; but as a means to the end desired, it is infinitely preferable to the original bill.

If the Senate sincerely wishes to promote American shipping, let it do something that is at least statesmanlike and consistent with that high standard of international morality which the citizens of this great republic still fondly believe to be one of our greatest national assets.

Archeology, Sulphur, and Cyrene

GREAT industries have often been associated with the elements of physical danger confronting those who engage to further them. The hazard is ten-fold increased when the operations are carried to, and even beyond, the frontiers of civilization. The history of every great enterprise of European or American capitalization that has spread to remote lands and alien peoples, records death and suffering.

To ascribe to the competition within the zone of civilization of two great industries the untimely death of an American citizen not even remotely identified with those industries and laboring in archeological research on a bleak stretch of North African coast would be to presume upon the credulity of a reader of fiction. But an instance of the truth that is "stranger than fiction" is revealed by the train of circumstances that led to the murder at Cyrene, in Tripolitania, a year and a half ago, of Herbert Fletcher DeCou, of Michigan.

In the columns of this issue of the SCIENTIFIC AMERICAN there is marshaled indisputable evidence to show that DeCou, who was a member of the expedition sent to Cyrenaica by the Archeological Institute of America, met his fate indirectly as the result of the legitimate, but none the less determined, rivalry between the centuries-old sulphur industry of Sicily and the sulphur industry of Louisiana, youngest of America's "infant industries." The evidence also goes far toward establishing the fact that the inordinate Sicilian fear and suspicion born of that industrial conflict was a contributory cause of the present war between Italy and Turkey.

DeCou was plainly an innocent victim of circumstances that, for the most part, operated quite without his sphere of life, but that in an evil hour shifted only to center upon the desolate Acropolis of Cyrene, where he toiled with a scholar's rapt enthusiasm on behalf, not of industry, not of commerce, but of the science of antiquities. His lonely grave on the face of the plateau of Cyrene, "looking out westward, toward the homeland," to quote the description reported to the Archeological Institute of America by Prof. Richard Norton, of Harvard University, who directed the expedition, bears mute, but eloquent, testimony to the fact that the life-risk which attends the onward march of modern industry may, by an abortive sequence of events, find a sacrificial victim even in the pursuer of a totally divergent calling.

How deep-seated was the antagonism which the presence of the American expedition at a point several hundred miles away from the coveted sulphur region of Gebel-el-Gebrit created in certain Italian quarters is to be gauged from Prof. Norton's report of the trials which beset the party in their efforts to obtain an actual start of operations on the site of Cyrene. The Senussi tribesmen whom they employed levied upon them for an exorbitant wage, and concerning this the director observed.

The reason why I agreed to this high rate (10 piasters or about 30 cents a day) was that I wished to convince the Arabs, as soon as possible, of the advantage to be derived from our presence. One reason that they demanded it was that reports had come to them from Benghazi that if they refused to work for us and forced us to depart, our concession would be taken up by Italians, who would pay them one *mejidie* (about $1) per day.

Of noteworthy interest, also, is Prof. Norton's statement that "there is reason to suppose the bullets were intended for the director, and that the purpose was to thwart the undertaking by driving the Americans from the country."

The fact remains that the immediate cause of the DeCou tragedy was a criminal plot against American life and an American undertaking. Suspicion points to Sicilian influence in, if not direct Sicilian instigation of the murder. The current recital of the history of the Sicilian sulphur industry, which has always been closely identified with the political life of the island principality, demonstrates how serious, how vital a menace American control of the sulphur deposits of Cyrenaica must have seemed to the Sicilians. It must have loomed to the stature of economic disaster before their affrighted gaze. In the light, or rather the shadow, of so grave an impending catastrophe, their energetic protests to Rome and the violent utterances of their local press were justified.

Had Cyrenaica been under any civilized dominion, it would have been a relatively easy task for Italy's diplomatic representatives abroad to definitely ascertain whether, as the Sicilians feared, a concession for the exploitation of sulphur in Cyrenaica had been granted to the Americans. [illegible] the excitement of Sicily would have been allayed.

But the Italian Government was dealing with the Porte, whose power and strength have ever been derived from secret intrigue, falsehood and dishonesty. Instead of frankly meeting Italy's rightful inquiry upon the subject, the Ottoman authorities proceeded to make a fancied capital of the suspicion and disquietude of the Italians—to their great cost, as it has since proved. The war followed, and a fearful toll of Arab life is avenging Turkey's deliberate sacrifice of the life of DeCou.

The Use of Ozone for Purifying Air

SOME very satisfactory results have of recent times been obtained by the use of ozone as a disinfectant and deodorizer for impure air, such as has to be reckoned with in crowded halls, in certain industrial workshops and in other places. The use of ozone, however, has its limitations, and in order to successfully and intelligently apply this agent, it is necessary to understand these limitations. The subject is discussed in a paper by M. O. Troy, published in the *General Electric Review*. Experiments on the effect of ozone upon bacterial cultures have shown that the bacteria near the surface of the culture may be more or less completely destroyed, while the deep-seated bacteria are affected but little or not at all. This is only what we should expect, for ozone, coming in contact with the organic material of the culture medium, oxidizes the same, and is at the same time itself reduced to ordinary oxygen. Thus there is no opportunity for any ozone to reach the bacteria in the deeper layers of the medium. As regards more particularly the action of ozone upon impure air, it must be remembered that the ozone will not only attack bacteria and other bodies which it is intended to destroy, but will at the same time act upon all organic matter present, some of which might have been removed by other, cheaper means, such as filtering. It is needless to point out that it is sheer waste to consume considerable quantities of ozone in the oxidation of such removable impurities, to say nothing of the fact that these may take up all the ozone supplied, giving it no opportunity to react satisfactorily upon the substances for which it is particularly intended.

As for the field of usefulness of the ozonizing process, it has already been pointed out that this extends particularly to crowded rooms and workshops. As special examples of the latter may be mentioned, the shops for assorting rags, factories for the manufacture of fertilizers, and those which work gelatine, glue, hides, hair, fat, bones, horn and other slaughter-house by-products. Such installations, the emanations from which constitute a nuisance and a menace to the public health, may with great profit apply the ozone treatment.

Several instances are on record in this country, in which the ozone treatment not only proved a very efficient remedy for conditions of bad air, but did so in circumstances in which other means had failed, or were for some reason inapplicable. Thus a moving picture show in Schenectady had experienced difficulties with its ventilation. The management were very desirous of providing the best ventilation possible, and had gone to considerable trouble in setting up the requisite equipment, but all to no avail. A larger blower could not be installed without giving rise to objectionable draughts. As a solution of the trouble an ozonizer was installed, with the result that the air in the theater is now perfectly sweet and odorless, except for a faint and rather pleasant smell due to the small excess of ozone. Similar results were obtained in a workshop, the air of which was at times rendered uninhabitable by vapors arising from a solvent used in the process of manufacture. Not only was in this instance the desired relief obtained, but a costly system of draught pipes previously installed could now be dispensed with. In another case a store was invaded by clouds of smoke from a fire in an adjacent building, and the owners saw before them the prospect of much loss owing to the difficulty of eliminating the odor of smoke from the rooms and from the goods. Here also, an ozonizer completely saved the situation.

In the sterilization of air, the ozone should be blown into the apartment, or the air should be drawn through a special chamber in which the ozone is mixed with it. It is important that the ozone come freely into contact with each individual particle which it is desired to destroy.

The machine for producing the ozone should not produce any nitrous oxide or any other gas having an untoward action on the human organism.

The generation of ozone should continue until the air, as determined by experimental test, is thoroughly sterilized, and the machine should produce this result without loading the atmosphere with ozone to an injurious concentration.

Engineering

The Bicycle Holds Its Own.—Statistics recently published show that the bicycle is more than holding its own in France. It seems that the total number in that country for 1910 was 2,607,4[illegible], and that this had increased in 1911 to [illegible]. Although, as a means of recreation, the bicycle still survives in Europe only, it is certain that both in the eastern and western hemispheres it has taken a permanent position as a useful means of travel, particularly for the artisan population.

Oil-fired Battleships.—The new battle ships "Nevada" and "Oklahoma," which were recently illustrated in the SCIENTIFIC AMERICAN, are to burn fuel oil exclusively; and naval officers will watch the results of this new venture with keen attention. The advantages are many: fireroom weights have been decreased about 300 tons; there is a decrease in the weight of fuel for a given steaming radius as compared with coal, and there is a decrease in the fireroom force of about 50 per cent. Very valuable also is the saving in the length of space required for the boilers and firerooms. For coal firing 128 feet of the ship's length would be required, whereas with oil firing the length of the "Nevada's" boiler rooms will be only 86 feet.

The Largest Sidewheel Passenger Steamer.—Very interesting is the continual increase in the size of both freight and passenger steamers which is noticeable on the Great Lakes. The new steamship, "City of Detroit III," which is now in commission, is the largest sidewheel passenger steamship in the world to-day. In the history of steamship construction she has only been exceeded once, and that was by the "Great Eastern," which was 692 feet in length. The "Great Eastern," however, was both paddle- and screw-propelled. The "City of Detroit III" is 500 feet over all, 55 feet broad molded, 100 feet over the guards, and she has a molded depth of 22 feet. We shall have more to say on this fine vessel at a later date.

The Clyde and the Diesel Engine.—According to the *London Times*, the Clyde shipbuilders have an objection against the Diesel engine on the ground of its lack of flexibility as compared with the steam engine, claiming that it must be kept running at a fair speed or it will stop altogether, whereas the steam engine can be run either ahead or astern at any slow speed desired. The makers of reciprocating engines of the smaller marine type state that this is the principal reason why the oil motor is not making more headway. But a Diesel engine consumes less than half the amount of fuel and is in every respect far more economical, and hence it is certain that the objection above named will be met and fully mastered; indeed, the reduction gear would solve the problem at once.

German Naval Increase.—At the last annual meeting of the German Navy League, under Admiral von Koster, the president, in his opening speech, stated that the new navy law provided that by 1917 there would be in the navy forty-one battleships and twenty armored cruisers. Yet, in the face of these facts and of our recent emphatic reassertion of the Monroe Doctrine, there is a determined attempt to prevent the construction this year of our moderate naval programme of two battleships per annum. The people of the United States, we firmly believe, are thoroughly in favor of the moderate two-ship program. Taxpayers throughout the country should give their representatives in Congress to understand that the proposed cessation of building is extremely unpopular.

Vehicle and Pedestrian Traffic.—Any one who is abroad on the streets of lower New York at the noon hour—at any hour of the day, for that matter—must feel that the time is near when the question of providing further foot-passenger accommodation is very near at hand. We have frequently advocated the separation of pedestrian from vehicular traffic. The simplest way to do this would be to double-deck the streets, not necessarily across their full width, but by providing above each sidewalk additional sidewalks for foot passengers at the level of the first floor. Apart from the loosening up of congestion which would be secured by this arrangement, the provision of sheltered sidewalks at street level would be greatly appreciated, especially during the rainy weather.

First Voyage of the "Selandia."—An inspection of the Diesel engines of the "Selandia" at the conclusion of her first round voyage (of 21,840 miles) shows that they went through the trial with most satisfactory results. No defects whatever of a mechanical character were developed, and both the navigating and engineering officers speak in the highest terms of the performance of the vessel. The piston rings and the cylinders were found to be perfectly clean; the exhaust valves, according to the engineers, were examined twice and most of them needed nothing more than to be cleaned and ground in. The voyage, says *The Engineer*, has shown that 9,300 tons of cargo can be carried a distance of nearly 22,000 miles on a consumption of 9 tons of fuel for each day of 24 hours. This was done, moreover, with an engine-room crew of ten men and three boys.

Electricity

Wireless in Siberia.—The extreme northeastern corner of Siberia will be in radiotelegraphic communication with Vladivostok by the end of the present summer. Stations are in course of erection at Mayahama and at Novo-Markovo, at the mouth of the Anadyr River.

Shocks from Pole Lines Exposed to Electric Waves.—That high power Hertzian waves emitted by modern wireless telegraph stations are capable of setting up high electromotive forces in metal structures in the immediate vicinity of the stations, was recently shown in Paris. Some workmen on a section of telegraph line experienced severe shocks when they touched the wires. Investigation showed that the source was the great Eiffel Tower wireless station.

Ignition of Mine Gases by Electric Spark.—Many accidental explosions may be traced to the "touching off" of gases by electric sparks. A recent colliery explosion appears to have been caused by the tiny sparks at the trembler contact of an ordinary electric bell; the accident emphasizing the need for providing absolutely sparkless electrical apparatus of all kinds in mines, factories, or anywhere that explosive atmospheres are likely to exist.

Electrical Means of Destroying Marine Boring Worms.—A way has been found to check the ravages of the teredo in destroying wood structures such as the submerged piling of wharves by means of a special floating electric power plant connected to submerged electrodes permanently wired to the wharf. Chlorine gas is electrolytically generated in the salt water, and the chlorine effectually cleans out the colony of teredos which are attacking the wood. An occasional treatment only is sufficient.

The Largest Single-phase Locomotives.—The most powerful single-unit electric locomotives that have been designed up to the present time are now being built for a Swiss railway. These locomotives, ten in number, weigh 108 tons each, total, and have a weight on their ten drivers (adhesive weight) of 85 tons. They are capable of developing 2,500 horse-power at a speed of fifty miles per hour, with a possible increase of speed to seventy-five miles per hour, for an uninterrupted run of 1½ hours, and can exert a drawbar pull of 18,000 kilogrammes from the standstill.

Electrolysis Ordinance in Chicago.—The city council of Chicago has recently passed an ordinance requiring certain electrical equipment to prevent damage by electrolysis. It requires that the difference of potential between any two points on a return circuit must not exceed twelve volts and between any two points on the return a thousand feet apart, within one mile radius of the city hall shall not exceed the limit of one volt, while between any two points on the return seven hundred feet apart, outside of this mile radius, it will not exceed the limit of one volt. Return current amperage on pipe and cable sheaths must not be more than five tenths ampere per pound-foot for caulked cast iron pipe, and eight amperes per pound-foot for screwed wrought iron pipe, and sixteen amperes per pound for standard lead or lead-alloy sheaths of cable.

Wireless Distress Calls Not to Go Unheard.—One of the most noteworthy steps taken during the International Radio-Telegraphic Conference which opened in London June 4th and closed July 5th is the laying down of a practical rule for attendance on the wireless apparatus on shipboard. It will be recalled that the "Titanic's" distress signals went unheard by vessels in the immediate vicinity because the single operator employed on those ships was off duty at the time. Under the Conference rule, a permanent watch is required on ships of the first class, which means that two operators must be employed, and on ships of the second class, employing only one operator, the receiving apparatus must be attended during the first ten minutes of each hour. In order to allow the operator to have his rest unbroken when off duty, this provision will probably mean that one of the crew trained to receive the distress signal, will be required to listen during the ten minutes beginning each hour.

Fusing Platinum in Quartz.—How to fuse platinum wires into quartz tubes, so as to make a good joint, is no small problem. M. Berlemont presented his new method to the Academie des Sciences not long since, and claims to have been successful. The difficulty is that quartz melts at as high a heat as ,800 deg. Cent. and has a very small expansion value, while all the metals expand to a much greater extent and also melt at a lower temperature. After numerous attempts to make a joint, first by direct fusion, and then by an indirect method, such as the use of glass or enamel, oxides or electrolytic deposits between the wire and the quartz, M. Berlemont came back to the direct method of imbedding the metal in the quartz, using a platinum-iridium alloy. By an improved process, requiring some skill, he could make a tight fused joint which would stand a high heat without damage, and was thus able to make all kinds of quartz tubes with fused electrodes.

Aeronautics

Hydro-aeroplanes at Aix-les-Bains.—The municipality of Aix-les-Bains, one of the principle watering places in France, is engaged in organizing a concourse of hydro-aeroplanes with the aid of the Aero Club Flights will be made upon the Bourget Lake on this occasion, from September 14th to 20th, and there will be several prizes, amounting to a total of $10,000. All the flights are to take place on this picturesque lake and the event will no doubt be an attractive one.

A Flying Corps Bill.—The House of Representatives recently passed a bill authorizing the detail of thirty naval officers and thirty army officers for aviation duty at double their regular pay. Officers of the Marine Corps are included in the authorization to the Navy. The length of the detail is made four years, but it may be renewed. It is also stipulated that at any time an officer so detailed may be sent back to his regular duty if for some reason he should become unfitted for flying

A British Aeroplane Gun.—Experiments with a quick-firing gun in an aeroplane were made by the Royal Flying Corps at Farnborough, on July 25th. The test was made in a stiff breeze at a height of about four hundred feet. Some twenty rounds of ammunition were fired at imaginary objects on the plain directly beneath the aeroplane. The recoil is said to have had but little effect upon the steadiness of the machine A biplane was used, built in the army factory. It was especially strengthened in order to carry the weight of the gun and ammunition.

The First Theft of an Aeroplane.—The first case of stealing an aeroplane occurred not long ago at the Puchem aerodrome at Munich. When the pilot, Belat, arrived in the morning he found that some one had broken into his hangar and that the monoplane was missing On inquiry he found that several persons in the neighborhood had heard the noise of a motor about 2 o'clock in the morning. Apparently some enterprising pilot had flown away with the machine. In the suburbs of Munich policemen were kept busy scanning the horizon in search of the flyer. Up to the present writing the machine had not been recovered.

Statistics of French Balloon Ascensions.—Figures show that the number of balloon ascensions in France during the first six months of this year is greater than ever before, this referring to spherical balloons. From January 1st to June 30th, there were made two hundred and fourteen ascensions, for which the amount of gas used was 243,000 cubic meters (7,300,000 cubic feet) The number of persons taking part in these ascensions was six hundred and thirteen, of which there are counted one hundred and twenty-eight officers appointed for the purpose by the War Department, also ninety-seven women aeronauts.

Proposed Aeroplane Flight from London to India.—The Peking-Paris aeroplane flight for which a prize has been offered by the Paris *Matin* has inspired English aviators with the project of arranging a flight from London to India, and a committee has been organized in London to push the scheme The proposed route is across Germany to Vienna, thence by way of the Shipka Pass and Adrianople to Constantinople; then along the route of the Anatolia Railway to Aleppo; thence to Bagdad; thence along the shores of the Persian Gulf and the Arabian Sea to Karachi; a total distance of 4,500 miles. It is expected that at least three aviators will take part.

The Coming French Show.—The fourth international aeronautic show which will be held at Paris in the Grand Palace is likely to outdo its predecessors in interest As to the decoration, it is proposed to use the new aeroplanes which are being built by public subscription for the army. These will be hung in an attractive way so as to make quite an impression upon visitors. It is not certain, however, whether this plan will be realized. As regards the exhibits, these are divided into thirteen groups, comprising spherical balloons and airships, aeroplanes, motors and helices, scientific work and apparatus, works of art, material and machine tools, transport and shelter, maps and books, commerce, various industries and manufactured objects, motor-boats, societies, touring.

Biplanes for Greece.—The fleet of biplanes which H. Farman's establishment delivered to the Greek Government not long since for military use is now engaged in very good flights in that country. More recently, Lieut. Kamberos mounted on one of the biplanes, which was transformed to a hydroplane, set out to make the over-sea flight from Athens to Hydra, the distance being about 50 miles Starting from the port of Phaleros at 9 o'clock in the morning, he sailed above the Salonique Gulf and then rose to a great height and flew toward Hydra in spite of a very stormy wind. The torpedo boat "Nike" accompanied him. He alighted at the port of Hydra, after making the trip in forty-three minutes at an average speed of fifty-five miles an hour, and he flew back to Athens on the following day.

Sulphur at Home and Abróad

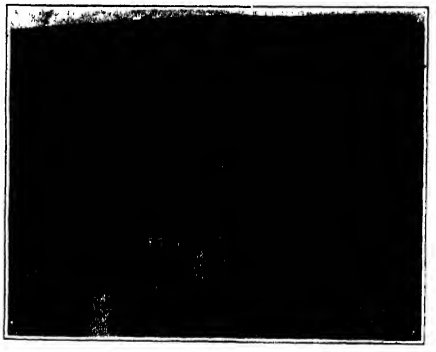
A Contrast Between American and Sicilian Methods

By Harry Chapin Plummer

SICILY'S sulphur production centers in the southerly angle of the island and comprises an area about equal to that of the State of Connecticut. A population of 500,000 is directly dependent upon the industry, and of this at least 350,000 are ignorant, ill-nourished peasants, called "carusi," who labor in the mines.

The minable deposits extend from Centuripe, in the Province of Catania, on the east, to Gibellina (Province of Trapani) on the west, and southward as far as the coast. The richer deposits, all under operation, occur within an area of from 90 to 105 miles in length, and from 53 to 56 miles in width. The sulphur, which in structure is massive, or coarsely crystalline, but usually compact, is found chiefly in an argillaceous limestone, associated with gypsum and bituminous marl. The sulphur-bearing rock takes the form, not of extensive beds, but of immense lenses of variable thickness and richness, and there are usually present from three to four sulphur layers.

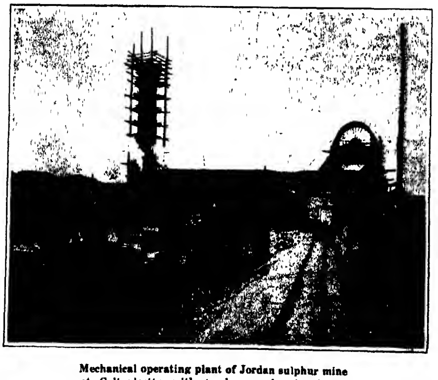
Exceedingly crude and simple methods prevail, and have prevailed since the days of the Romans, in the mining of Sicilian sulphur. Steps hewn out of the rock lead to tortuous and disordered subterranean galleries attaining to depths of from 500 to 825 feet, but averaging about 600 feet. The crude ore is heated to the melting point of 115 deg. Cent., and collected as it is run off. There are two methods by which the sulphur is heated: one, by burning part of the mineral in what are locally termed *calcaroni*, or beehive ovens; the other by means of superheated steam forced into the deposits by hydraulic pressure, somewhat after the system in vogue at the American sulphur wells in Louisiana.



Mined lumps of sulphur at base of mounds, Caltanisetta, and calcaroni, primitive ovens in which the sulphur is heated.

One of the most drastic moves in the history of the Italian Parliament was made necessary by a crisis that arose in Sicily in 1906. It was the passage of an act by which the 180 sulphur producers of the island were forced to combine in a *consortium*, or state trust, and thereafter to deliver their product over to the Government, as mined. Among the members of this trust, which is known as the Consorzio Obbligatorio Zolfifero Siciliano, are princes, senators, and deputies of Sicily, and a one-time minister for foreign affairs of Italy.

The Sicilian industry, debilitated by



Mechanical operating plant of Jordan sulphur mine at Caltanisetta, with trackage and coke dump.

Molded cakes of refined sulphur cooling near smelter at Caltanisetta; atop of them two typical "carusi," or boy miners.

This is a huge bin forty-eight feet high and two hundred feet long into which liquid sulphur is being pumped.

Loading a vessel with Louisiana sulphur at the rate of sixteen tons a minute. Contrast this with the method of loading Sicilian sulphur.

...of market speculation, usury and ...al *vendette*, late in the last century, staggered under the shock of news of the opening up of an immense deposit of sulphur on the gulf coastal plain of Louisiana.

By Herman Frasch's invention of a process for liquefying sulphur in the ground, at a depth of 1,000 feet, and pumping it to the surface in fluid form, an immense alluvial deposit of sulphur in Calcasieu parish, Louisiana, on the Gulf of Mexico, was opened up in 1893. The deposit was in the form of a volcanic cone, the apex of which was 800 feet from the surface An eminent Italian engineer, Dr. Baldacci, delegated by his Government to investigate the report of the discovery, that had quickly reached Europe, not only confirmed it, but estimated the newly found store to aggregate 40,000,000 tons, or more than sufficient to meet the world's requirements for an entire generation. What most alarmed the Sicilians, however, was the fact, as reported by Dr. Baldacci, that the Louisiana sulphur was produced at an average cost of $3.68 per ton, as against $12 per ton, the cost of mining sulphur in Sicily Water, superheated to 350 deg Fahr, was sent into the ground in Louisiana, in columns wherein a pressure of one hundred pounds per square inch was maintained. When dissolution was effected, the liquid sulphur was pumped into great bins of about 150 by 250 feet, where it solidified to the consistency of sandstone, and awaited the attack of workmen to break it up, by blasting, for shipment.

The wells were sunk in groups, the individual wells being placed fifty to one hundred feet apart, and a single well would be found to have a daily production of four hundred to five hundred feet of sulphur and to keep up a steady flow for months at a time. The liquid sulphur as it flowed from the well was so pure that the company was able to guarantee a sulphur content of 99½ per cent, but the average purity well exceeded that figure.

Twenty 150 horse-power boilers were used for a single well, and this represented experimentation on a ponderous scale. The number of boilers employed to superheat the water used in the pumping has since been increased to 130, each of 150 to 300 horse-power, and arranged in eight batteries, containing with one exception 15 to 20 boilers each, and each battery of boilers capable of operating a well. Two of these batteries are placed in a group, so that one foreman can oversee both. The boilers are fired exclusively with fuel oil, pumped from wells located on the premises, and only three men, two firemen and one water tender, are required on each shift to the firing and the feed water in each battery. Similarly great economies have been effected in the dispatching of the sulphur for shipment. A flat car receives a load of thirty-five tons within fifteen minutes, while at the company's

Locomotive derrick in Louisiana taking up its charge of sulphur two tons at a time.

docks at Sabine Pass, Tex., about fifty miles away, one man is enabled to effect the automatic discharge of an entire train load in a few minutes, unassisted, and chartered steamships and, of late years, vessels of the company's own fleet have loaded more than ten tons per minute and sailed, laden with cargoes of 7,000 tons each, within twenty-four hours after arrival at Sabine Pass A striking contrast to the slow, laborious method of transferring the sulphur from the Sicilian stores at Porto Empidocle and Catania to waiting ships by hand, in baskets of but a few bushels each!

Confronted by this sudden development of a formidable competition in 1905, the Italian Government realized the seriousness of the situation It learned that the newly born sulphur interest, youngest of America's "infant industries," had not only intrenched itself in the markets of the United States and Canada, hitherto monopolized by the Sicilian product, but that it had begun an aggressive campaign in the European field It had even built at Marseilles a great refinery for the treatment of the Louisiana sulphur, brought to the French port in its own ships.

Premier Luzzati, who was then at the helm of Italy's Ship of State, resolved upon a step which showed how critical he regarded the situation that existed. He sought out the head of the American interest, Herman Frasch, the "wizard" of the Louisiana wells, who journeyed from Marseilles to Rome upon the invitation of the great statesman

In the course of a memorable conference between the two, the Italian Prime Minister dwelt upon the economic significance of the plight in which the Sicilians found themselves.

Frasch pledged his company to restrict their operations on the continent of Europe to such consumers as they had already contracted with, provided that the Sicilians would abandon the American field.

The organization of the Consortium, or state trust, followed, with the resulting shut-down of 120 of the 484 mines. The employees of these, the smaller of the island's mines, were disbanded But the attendant privation was minimized and the extreme results that the Government feared were obviated. Most of the laborers forced out of employment later swelled the tide of Sicilian emigration to the United States.

The production of Sicilian sulphur reached its high-water mark in 1905, with a total of 570,000 metric tons for that year, as against 390,000 tons in 1881 and 112,000 tons in 1860; but after the conclusion of the agreement between the Consortium and the Union Sulphur Company, the production diminished, and in 1909 totaled only 400,000 tons. At the beginning of the present century the produc-

(Concluded on page 150.)

Sugar Beet Industry of Germany

What Science Has Done for a Great Industry

By H. C. Price

Germany is the home of the sugar beet industry. It has about 400 sugar factories with a total average annual production of over 2,000,000 tons of sugar, about one half of which is exported. Sugar beet growing is the most profitable type of farming followed in Germany, and probably has done more than anything else to bring about the excellent type of intensive farming for which central Germany is so justly noted. The province of Saxony is in the heart of the sugar beet growing of Germany, and although it contains less than 10,000 square miles there are over 200 sugar factories in it. Good sugar beet land is worth $500 per acre, and the returns from sugar beet farming are large. This article is both a historical review and a summary of the technical methods that have elevated the sugar beet industry to its present eminence.—EDITOR.

THE beginning of the manufacture of sugar from beets is a direct result of the Napoleonic wars. In 1747 Marggraf, a German chemist, discovered that the common white field beet of Germany contained sugar, but this discovery was not considered as of any economic importance. But in the beginning of the nineteenth century, when Napoleon Bonaparte was in the zenith of his power, he put an embargo on the importation of sugar into Europe in order to strike a blow at England, since practically all of the sugar used in Europe came from the British colonies. This resulted in famine prices for sugar, and now for the first time Marggraf's discovery was thought to be of some economic value, and that possibly the beet might be utilized as a source of sugar. As a result, in 1812 a factory, the first of its kind in the world, was built near Breslau, Germany, for the manufacture of sugar from beets. In France likewise factories were soon built, and under the stimulus of war prices and government protection the new industry was established.

Since 1890 the average annual world's production of beet sugar has exceeded the annual production of cane sugar, and in 1910 the world's production of beet sugar exceeded 8,500,000 tons, or seventeen billion pounds.

The development in so short a time of the sugar beet as a source of human food is not equaled by any other plant anywhere in history.

Increase of the Sugar Content of the Beet

In 1812, when the first sugar was manufactured from beets, it took twenty tons of beets to produce one ton of sugar, and at the present time it only requires about six tons. This decrease in the amount of beets required to produce one ton of sugar has been due to two things: (1) more perfect methods of manufacture, and (2) to a higher percentage content of sugar in the beet, principally to the latter. This increase of sugar content has been the result of scientific plant breeding, and the results that have been attained in this line are the most remarkable and economically the most important that have ever been accomplished through the science of plant breeding. Beginning with a plant that did not contain over 5 per cent of sugar, systematic selection by the plant breeder has produced a strain that sometimes contains as high as 25 per cent of sugar, and the average for an entire crop season in Germany has been as high as 17 per cent, as was the case in 1910.

That this immense increase in the sugar content has been the development principally of the last few decades is shown by the following table giving the percentage of sugar found in beets that were produced under the most favorable European conditions:

Percentage of Sugar Contained in Beets by Decades

Year	Sugar	Year	Sugar
1838	8.8%	1878	11.7%
1848	9.8%	1888	11.7%
1858	10.1	1898	15.2%
1868	10.1	1908	18.1%

In America equally high percentages of sugar have been secured, in some cases even higher.

Production of Beet Seed.

The sugar beet is especially well adapted to breeding, since a test can be made of the sugar content of the individual without destroying it for the production of seed. The beet is a biennial plant, making its growth the first season and the following year producing seed. In selecting beets for sugar content they are harvested in the fall and in the laboratory a small section is bored out [illegible] beet and tested for its sugar [illegible]. This shows the sugar content of [illegible] dividual beet, and it is not injured [illegible] the production of seed the [illegible] spring. In this manner selections [illegible] made from generation to [illegible] pure strains and varieties [illegible]. Special beet breeding farms have [illegible] established in France and Germany [illegible] hundreds of thousands of individual [illegible] are tested each year. The [illegible] these farms is at Klein W[illegible] central Germany, where 12,000 [illegible] under cultivation and over fifty [illegible] beet breeding has been carried on [illegible] the most careful and scientific supervision.

The "plant" at Klein-Wanzleben, Germany, the largest beet breeding establishment in the world. The sugar factory, laboratories, seed warehouses and administration buildings.

Beet breeding laboratory at Klein-Wanzleben, Germany, for testing individual beets for sugar content.

Women harvesting beets. The type of laborers that are brought in from other provinces for the season.

Increase in Consumption of Sugar.

The world's consumption of sugar is now eight times as much as it was fifty years ago. From being regarded as a luxury, sugar has come to be a necessity in the every day diet of practically all civilized nations. It is the one product for which every individual seems to have a natural taste, and it is more generally liked by children than any other substance. The amount consumed varies greatly in the different countries, and as a rule is in proportion to the degree of civilization and average wealth of the nation. England and the United States have been far in the lead in the per capita consumption, as shown below, and are the heaviest importers.

Per Capita Consumption of Sugar in Pounds Per Annum.

England	89.5
United States	74.8
Switzerland	58.1
Denmark	56.7
Norway and Sweden	41.7
Holland	38.0
Austria-Hungary	37.2
Germany	36.9
France	36.0
Belgium	27.9
Russia	16.6
Spain	10.2
Turkey	8.2
Italy	7.7

There is no distinguishable difference between beet sugar and cane sugar as they appear on the market. They are entirely interchangeable, and the only determining factor in their use is the price at which they are sold. Although the production of cane sugar has increased rapidly, beet sugar production has advanced with a much greater rate of speed until now over one half the world's supply comes from beets. The increase in the world's production and the relative amount produced from sugar cane and from sugar beets during the last fifty years is shown in the following table:

World's Production of Cane and Beet Sugar in 1,000 Tons

Year	Cane	Beet.	Total	Proportion Beet Sugar
1860..	1,376	390	1,766	22.1
1870..	1,856	844	2,700	31.3
1880	2,084	1,531	3,615	42.4
1890	2,522	3,537	6,059	58.4
1900 .	2,978	5,440	8,418	64.6
1910.	6,236	8,471	14,707	57.6

The Labor Problem in Sugar Beet Culture.

The greatest drawback to the growing of sugar beets in America has been the labor problem. A large amount of hand labor is required, and in America this labor has not been available. In Germany it is done largely by women. According to the census of 1906 there were 5,500,000 farm hands in Germany, exclusive of the owners of the farms, and their families, and of this number 2,500,000 were women.

...r of the SCIENTIFIC AMERICAN:

...nt editorial on the "Titanic" reminds me ...o you what I wrote to the chairman of the ... Investigating Committee, but have not seen ... any newspaper.

... a large ship, like "Titanic," moving swiftly, ... a large iceberg, the principal danger and the ...pal damage would *not* be in the crumpling of the ...or the flooding of several compartments, but in the ...vior of the boilers and secondary to that the be...or of the engines.

When the forward motion of the ship is suddenly ...pped nothing whatever could hold boilers and engines ... breaking loose and going forward and smashing the ...lkheads and probably the bottoms.

But in addition to this the boilers must break the steam ... and must immediately explode, and this would ...roy the ship.

This is submitted to your consideration, although it may be old. W. S. PROSSER.

San Jose, Cal.

[In his testimony at the Board of Trade Inquiry, London, the designer of the "Titanic" stated that if the ship had struck bows on, she would have crumpled up about 100 feet of her bow and would have taken several seconds to come to a state of rest. He stated further that the blow would have been so greatly cushioned that the machinery would not have been displaced.—EDITOR.]

A Word to the Socially Unfit

To the Editor of the SCIENTIFIC AMERICAN:

Kindly allow me to say a few words suggested by your editorial entitled "Lunacy and Morals," in your issue of July 13th.

From the deterministic, the only thoroughly scientific standpoint, there is no "line separating responsible wickedness from acts against the public peace which have their origin in perversities of the psychic apparatus." Both result from peculiarites of structure, physical or psychical, which are often as much beyond the reach of medicine or surgery as they are beyond the reach of the subject himself.

Now that the old conception of punishment as social revenge has died out, in theory at least, the question is no longer whether one who is a public menace is "insane" or "immoral." The point is that he is a diseased element in the social organism, and as such should be removed. Scientifically speaking, a man is no more to be blamed for crime than for insanity. With the odds overwhelmingly against the man who oversteps the bounds of social conduct, as they are, he who does overstep those bounds reveals a weakness either of judgment or of self-control, both of which are allied to other forms of mental weakness. This, aside from the fact that the "perversion of the moral sense" is either congenital or the result of early influences.

The fault of the newer humanitarianism is not that it "now holds extreme views as to irresponsibility for criminal acts," but that it does not recognise that to declare a man to be insane does not make him less a social menace nor does it alter the fact that he has become what he is by the action of laws beyond his control. Neither does it alter the fact that the health of the social organism demands that he be removed therefrom, and removed effectually.

On this point the altruism which has done so much for our western civilization has degenerated into a harmful sentimentalism which places an excessive value upon the mere form of human life, regardless of the worth of that life to itself or to society. We take better care of our idiots, lunatics, and criminals than we do of our children. The last are left to chance until they become idiots, lunatics, or criminals, when they begin to receive the attention which comes too late. A rational and truly humanitarian policy would be to eliminate these elements by a painless death, which would end many miseries, protect society, and purify the social atmosphere. Vast energies would thus be left free to attack the problem of social regeneration at its root, the children. The social organism can never know its own possibilities until it has given every child an opportunity to grow up under the best possible conditions, physical, educational, and ethical, and it is time that public solicitude shifted more in this direction. PAUL R. BIRGE.

A Manufacturer's Views of Patents

To the Editor of the SCIENTIFIC AMERICAN:

Noticing in the papers that when Mr. Samuel O. Edmunds of New York city appeared before the Committee on Patents, he advocated making the date of filing the application on an invention the test of priority of the invention.

This might further the interest of justice in some rare cases, but I believe on the whole it would be a grievous mistake. It would result in the taking out of patents on thousands of unperfected, and consequently useless inventions. The theory of our present law is that unless the invention on a machine is something that will actually do the work intended, the patent is invalid. The theory is that the specifications and drawings shall show enough, so that a man with ordinary mechanical skill in the line to which the patent pertains may be able to construct a useful and operative machine.

If the original inventor did not apply for a patent on his first crude conceptions when he began experimenting, he would have to do everything under lock and key, and would always be in danger of having his conceptions patented by someone who found out what he was working on, so as to bar him from using it after he got it perfected.

It always takes a year, and usually two years, for me to make a material change in one of my machines. The change I am now making I have worked on steadily for three years, assisted by a corps of expert mechanics, during which time I have built over twenty models in reducing it to a practical and useful state of perfection. Under the present law I can do the work in the open, and have no fear of anyone stealing my invention.

I have been through a number of interference proceedings, and while they are expensive and annoying, I do not see any better way for insuring justice to all.

Sometimes I have grave doubts as to whether it is really very common to buy inventions for the purpose of suppressing them. It is true that concerns who have a large amount of money invested in special machinery and plant for the manufacture of a particular article, would be loath to make a change in that article which would involve a further large investment in tools and special machinery and the scrapping of a large portion of their original investment in this line. Perhaps a more serious determent is the fact that a change always involves the necessity of re-educating the staff and working forces to the production of something entirely new, during which period an inferior product is turned out and perhaps the reputation of the firm seriously injured. Also oftentimes things which, after long and careful testing, and which, viewed from every standpoint, appear to be practical, when put on the market, for some reason prove to be inferior to the original device. This is something that can scarcely ever be determined with a certainty until after some months or years in the field.

The fact that nearly all manufacturers of specialties, particularly those protected by patents, maintain expensive experimental departments, would tend to negative the theory that as a rule they desire to suppress new inventions. All such manufacturers receive weekly offers to sell patents on articles in their line or proposed improvements on their devices. Few, if any, offers are based on anything of any value whatever, and most of them have for their basis some impractical idea which has been offered by hundreds of others. There is one alleged improvement in the comptometer which has been offered to us on an average of once a week. This idea was tried out and discarded over twenty years ago and has since appeared in hundreds of adding and calculating machine patents. I have tried it out exhaustively on three separate occasions. Another was patented over twenty years ago. I manufactured it for a time, and found it to be of more damage than benefit. Yet continually I receive letters from men who think they have invented one or the other of these things, and that I am depriving the world of a great boon in refusing to turn over to them a factory and organization that has taken twenty-five years to build up, for the purpose of perfecting and putting their inventions on the market.

It would be utterly futile to try to explain to them why their ideas are impractical, and if one attempted to do so he would have time for nothing else, besides he would not succeed in convincing them. There was never yet suggested to me anything that I had not already considered and usually tried out exhaustively. I never bought any patent. Many a man has left my office with the statement that he was going after my scalp or that I would some day overlook a great opportunity by pursuing the course I do, only to some years after ask me to buy the machinery which he had purchased for the purpose of perfecting the manufacture of his supposed invention. If I had originally purchased his patent, he would always have believed that the purchase was only to suppress it. That class of inventor usually has little to do, so has time to make a good deal of noise, and a great many receive their statements at face value, hence the popular idea about buying up a patent to suppress it. Some manufacturers make a practice of buying up patents, but I do not believe that often they ever buy up anything of real merit for the purpose of suppressing it.

The cost of selling a patented article usually exceeds by far the cost of manufacturing. The public in its turn is very conservative, and as a rule all very meritorious inventions have to be forced onto the public—their introduction involves a tremendous amount of education. I believe that it is in this respect that patents have been beneficial to the public—much more so than from the tendency of our patent laws to encourage invention. If Congress should pass a law giving some firm the exclusive right to publish books treating of the method and use of the metric system and the exclusive right to make instruments for measuring and weighing by the metric system, in twenty years we would all be enjoying its benefits. As it is, no one can afford to introduce it, and Congress does not see fit to make its use compulsory.

It has been said that the greatest boon conferred on Christendom was conferred by Gerbert when, after disguising himself as a Mohammedan, he succeeded in obtaining admission to the Moorish universities, and after passing through two of them, returned into Christian Europe, bringing with him Arabic numerals. No one had a patent on their use, and for several hundred years they were not universally adopted, and school children could not be taught multiplication and division except in the small factors, which could be computed by mental perception with the use of pencil and paper. During that time, for business and engineering computations, everything was computed by the use of the abacus, such as is used by the Chinese and Russians to-day.

No one can question the value to mankind of the potato. Numerous explorers brought back to France, England, and Spain samples of the potato shortly after the discovery of America, but it was several hundred years before it became a common article of food, in spite of numerous recommendations by various great authorities that it be generally cultivated.

I do not believe a patent should be issued for any long period of time. I believe that seventeen years is about right. For some things the period is too short to enable those exploiting it to overcome the inertia of the public and reap any material benefits from the long years of labor, but no law can be so formed as to fit every possible case. What appear to be the most revolutionary inventions should be partly accredited to the inventor who first makes them practical and partly to the general advance in the mechanical arts. Seldom if ever has a revolutionary invention been brought out that has not been conceived and an attempt made to put it in material form hundreds of times before, only to fail either because the inventor has not the ability to perfect it or else mechanical arts are not advanced to a point where it could be successfully and economically manufactured.

Were it not for wars requiring the simultaneous manufacturing of large quantities of weapons, the sewing machine and the typewriter could never have been manufactured at a cost which would have made their purchase and use advisable. The machinery which has been evolved after many years for the manufacture of weapons had to be developed to a high point of efficiency before sewing machines and typewriters could be manufactured in large quantities and at a low cost. I can cite numerous other illustrations of this fact.

It is a serious question whether or not the one who pioneers a new art or invention does the public such a great injustice, even when he buys other inventions in the same line. The expense of pioneering is so great, that unless he has reasonable assurance of a monopoly which will warrant him in incurring the enormous expense of pioneering, he cannot afford to take the risk. I believe that a careful analysis will demonstrate that in those lines where a patent monopoly is the most complete, the public has received the most benefits and enjoys the most advantages in the way of improvement in quality of manufactured product.

Chicago, Ill. D. E. FELT.

Like most new things "natural gas gasoline" is the product of an imagination. For years it had been noticed that gasoline collected in the pipes into which the waste gases of oil wells had been turned. This "drip" was bought up by refineries. An imaginative inventor, John Lathrop Gray, made up his mind that he would find out why the "drip" accumulated at all. He found that gasoline could be squeezed out of natural gas, and took out the only patent which comprehensively covers the process now most widely used. This article, written by one intimately connected with the industry, explains the scientific principles of recovering gasoline from oil well gases.—EDITOR.

THE refining of petroleum oils as an art has been subject to a peculiar diversity of limitations. The infinite variety in physical characteristics of the crude oils which have been unearthed have imposed those limitations.

Crude oil may mean anything from an approach to asphaltum in character to the other extreme. An example representing the one extreme would be a dark brown or almost black substance having a pungent odor, the consistency of a thick molasses and a specific gravity of slightly more than 1000 as compared to water. A sample representing the other extreme would have a slight discoloration, only, from a pure white, and would be comparable in general appearance to the very lightest of sewing machine oils. So much for the liquid petroleum products which Nature has deposited for us.

In the majority of instances where petroleum is found, it is accompanied by more or less extensive deposits of natural gas. There are some exceptions in which petroleum is found alone. There are a great many cases in which gas is found not accompanied by petroleum, and many instances in which it cannot be shown that there is any physical connection between deposits of gas and oil.

It is an interesting but not greatly surprising fact that gases which are found residing with petroleum oils in the earth vary in physical characteristics almost as widely as do the oils which form the great family of liquid petroleum deposits, this with reference to specific gravity and variance of the relative percentages of the different hydrocarbon compounds of which the gas is composed.

Until about two years ago natural gases were estimated commercially as methane. It is a fact that the great volume of gas being produced and transported to large consuming centers may be so classed without great deviation from strict truth. Probably as much as 90 per cent by volume of the gas composition is methane, the remainder being ethane with very slight percentages in some cases of propane.

In dealing, however, with the gases which are found directly accompanying the petroleum oils as they reside in the strata from which they are obtained, we have a very different condition and a widely different general composition of gas. It is thought, now, that the variance in gas composition in adjacent oil wells is much greater than is that of the oils. Wells located within a narrow radius and producing, so far as can be observed, oils of uniform character from the different wells will produce gases which vary very markedly in percentages of the different hydrocarbons of which they are composed.

Within the last two years, a development has been carried to the proportions of an industry allied to refining, but which becomes necessarily a part of oil field operations, and it consists in the recovery of a refined gasoline which is extracted from oil well gases at the wells. There are a few exceptions to the statement that this product can be recovered from oil well gases only, but the writer believes that without exception it can be demonstrated that any gases which yield gasoline condensates to any considerable extent, communicate to and through oil producing strata. Since this phase of the petroleum industry has reached commercial proportions amounting to the recovery of probably some 2,000 barrels daily of a product which heretofore had gone to waste, it would be interesting to look into the physical conditions which make it possible. It will be most convenient to deal with the series of hydrocarbons known as saturated paraffins. It is possible that there may also be some exceptions to this latter classification.

If we consider, however, that a triangle may graphically represent the great family of saturated petroleum hydrocarbons, we can divide such a figure into percentages which may represent to the mind's eye, very clearly, the summary of facts involved.

We shall not permit the figure, or the percentages into which we divide it, to represent wholly relative volumes, but rather to represent combined volume and composition with reference to the structures forming the great group or family of petroleum hydrocarbons.

The dark base on which the triangle rests may represent the coke residue drawn from a petroleum still after the crude has been distilled into its various fractions; the second small percentage section of the triangle will represent petroleum tar and paraffin waxes; the third section, varying greatly in volume, may represent greases and lubricants; the fourth division may be made to represent lighting oils; the fifth, to represent naphthas; the sixth, to represent gasoline fractions; the seventh, to represent refinery products known as pentane, rhigolene, and cymogene. The eighth, to represent the heavy portions of condensible natural gases with which this article attempts to deal. The ninth division may be made to represent that portion of heavy gases which is intermediate between the product commercially accepted as gasoline and the great volume of gas product known as dry gas. The tenth and last division will be made to represent the methane portion, together with any impurities, of petroleum deposits, where gas and oil may be found in large volume. Such impurities as may be worthy of mention are carbon dioxide, free nitrogen, and some hydrogen sulphides.

To get a familiar conception of the chemical proportion of the compounds forming the triangular graphic representation, we may go to its base and look for a composition which is almost wholly carbon. The next division of the triangle will represent a product having a greater percentage of hydrogen and a lesser percentage of carbon in its make up, and when we have arrived at the third, or grease and lubricant division, we begin to find chemical compositions like $C_{24} H_{50}$ of the saturated series having the general form $C_n H_{2n} + 2$. The sixth group will bring us to a chemical composition with which we are quite familiar, viz., $C_7 H_{16}$, gasoline, naphtha, benzine. The seventh group will still further lower the relative carbon proportion, and we will have a range of compounds running from $C_6 H_{14}$ to $C_5 H_{12}$. The eighth division will represent our natural gas gasolines which are so closely related to the seventh group that it is not proper to designate them as different except as exceptions to this phase of the petroleum industry which we are considering now. The ninth group or division is to play an important future part in our domestic life. It represents that very considerable fraction of the greater number of oil well gases which can be liquefied by reasonable treatment and delivered in strong steel containers to isolated consumers for fuel and lighting purposes. The tenth and final division is $C H_4$ with the above-mentioned impurities, which exist to varying degrees in different localities, and are absent in the great majority of the important producing regions.

In getting a proper conception of this interesting matter, it must be borne in mind that the groups or divisions of petroleum products, unless subjected to extremely tedious treatment, are not sharply defined in chemical composition. This fact may be graphically represented again by the hypotenuse side of the triangle, which might represent the gradation from a hydrocarbon structure through all the minute steps from an all-carbon to an all-hydrogen composition, the hydrogen point being represented by the vortex of the triangle.

It is now easy to refer to and explain the method by which the product which is known as "natural gas gasoline' is recovered. For many years past in the operation of oil wells, where the gases escaping from them have been turned into a system of pipe lines for service, and the running of gas engines used to pump the wells, difficulty has been experienced under favorable winter weather conditions in those lines becoming filled with a liquid. Some water is frequently present, but more frequently the liquid found in the pipe lines

[illegible] to be gasoline. Many oil operations collect [illegible]ble quantities during the winter season of this [illegible]duct, which has been bought up by the refi[illegible] an inferior grade of gasoline. It obtained [illegible]on of inferiority from the fact that, in many [illegible]g lain in rusty pipes and come in contact [illegible]d dirty paraffin sediments, it has been dis[illegible] required filtering or redistillation. The [illegible] has, therefore, been content to receive [illegible]e one fourth to one third the [illegible]arket price for gasoline for [illegible]roduct, even though it be [illegible]and of apparently high grade [illegible]to refinery gasoline.

[illegible]l laws involved in the proc[illegible]ering gasoline from natural [illegible]posedly very simple. They [illegible]r to be the same as for the [illegible] of any liquid vapor sus[illegible] gaseous medium. The fact, [illegible]velops that the suspended [illegible]nt in natural gas being of [illegible] different chemical groupings [illegible]he matter somewhat and [illegible]he requirement of more ex[illegible]ment than the first glance [illegible]ve as necessary. Compress[illegible]ling of the gases containing [illegible]h suspension is all that is nec[illegible]ded the same be carried to a [illegible]tent and effected under prop[illegible]ent for the separating of the [illegible]e precipitated.

[illegible]ck to about the year 1906, we [illegible] investigators going further into [illegible]r than the application of vacuum [illegible] wells, and the recovery of the "drip" from lines connecting the pumps used to produce vacuum on the wells. They were employing air compressors to compress the gas to an extent much beyond that for which oil well vacuum pumps are designed to do duty. John Lathrop Gray obtained, apparently, the only patent which comprehensively covers the process, and the licensees under that patent seem to have found the most effective and extensive development of the industry.

The essentials of this Gray patent are the compressing and cooling of the gases, the separation of liquid products and the accomplishment of the same by the simplest and most effective means.

Gray used a simple type of separator for collecting the condensates, and an automatic trap which continually transferred the condensate to a place of storage.

The advantageous features of the method are greater than are seen at the first glance. One great difficulty in the development of the art has been to reduce the condensates to such a state of stability as will eliminate serious evaporation losses between points of production and consumption. It is now known that gasoline, either from petroleum oil or gas, will absorb considerable quantities of gas or even air, and that the absorption is a function of time, temperature and pressure.

Gray's method, therefore, of using traps to remove the condensates promptly, when precipitated, and minimizing the time of their exposure to gas under pressure, is of the utmost importance.

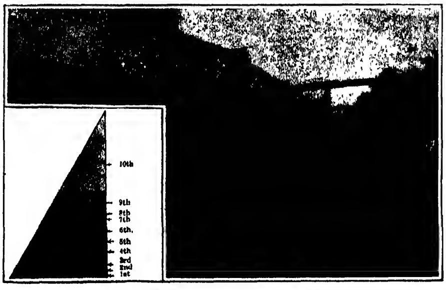
Just as in the case of crude petroleum oils, the new product, when produced by Gray's process, is capable of refinement to more homogeneous fractions. When to be handled as gasoline, the new product is very much improved by the removal of that portion embodied in a fraction which is too light and volatile to be stable at atmospheric pressure and the temperature conditions which must be met in use.

The recognition of new uses and increasing demand for the conservation of all fuel energy has held the promoters of the new industry to a realization of the necessity in providing means to effect the recovery and the separation into commercial fractions of the total product available. The possibility of fractionation by stage compression was early recognized by the writer, and many installations of machinery capable of ready adaptation to this method have been accomplished by the firm of manufacturers which has given the industry its greatest uplift.

The possibility of separation by stage compression treatment of a relatively large fraction of the product suitable for any fuel purpose, but which must be handled under restraint, brings about an entirely new phase of the petroleum industry which has not yet had scarcely more than an introduction to scientific and technical notice.

The successful introduction of the new product, which has been accepted as gasoline, depended largely on market conditions. It is comparable in inflammable characteristics to the highest grade refinery gasolines, and since its bulk has reached considerable proportions, the transportation of the same has received the attention of the Bureau of Explosives, and finally the Interstate Commerce Commission with certain restrictive safeguards which have placed its utilization at a premium, and the industry has been able to thrive only under the conditions of the consumers' demand which prevailed in 1910, and which now prevail. The whole year 1911 was one of plenty and predominant low prices of all petroleum products. The refiners were able to offer their product in serious competition with the new natural gas condensates to the extent of largely shutting its recognition out from the consumer.

The squeezers—direct driven straight line gas compressors, using for fuel residue gas after gasoline has been extracted.



Receiving tanks, in which the gases from oil wells are collected.

The insert shows triangle representing the great petroleum family. Taking out the 8th group which represents the heavy portions condensible to gasoline, the remaining residues are 1st —Petroleum Coke 2nd —Petroleum Tar and Wax. 3rd —Greases and Lubricants 4th —Lighting Oils 5th —Naphtha. 6th —Gasoline. 7th.—Refining products, Pentane, Rhigolene, Cyomogene 9th —Intermediate heavy gases. 10th.—Methane

Air and water cooled coils used in the condensing system.

The new product finds its best adaptation in the treatment of the refinery low grade gasoline fractions to make them suitable for motor fuels. Apparently, the new product will be sufficiently plentiful to bring the entire petroleum naphtha fraction, which is too low in gravity for successful motor fuel into a state of volatility making it entirely satisfactory, so far as carburetion and proper fuel mixture is concerned, and when so enlivened, this particular naphtha fraction has the greatest fuel value, having a greater weight for equal carbureting characteristics than any other known fuel.

The new product in appearance and physical characteristics is so nearly identical with the refinery first fractions, when properly produced and treated, that it requires careful judgment to distinguish it. The gravities of the natural gas condensates range from 76 degrees to 100 degrees Baumé (sp. gr. 0.68 to 0.61). It mixes permanently and without stratification with any refinery product which is not technically termed an oil. It also will mix sufficiently well with kerosene or lighting oil fractions to make a good satisfactory motor fuel, though, of course, such a mixture is not suitable for the cleaning of delicate fabrics where the presence of an oil would be objectionable. The term blending has been erroneously but conveniently adopted. The term itself would indicate the bringing together of two non-miscible materials. The light condensate is perfectly miscible with any "dry" or naphtha fraction and cannot be separated or re-obtained except by fractional distillation, and then only imperfectly.

The necessity for maintaining a cheap source of motor fuel will soon bring about the practice of "blending" the new "natural gasoline" or gas condensate with a 46 to 54 gravity lighting oil. Such a product will not be recognized or given proper credit, however, until the price of motor fuels makes it necessary to resort to such a means.

The very remarkable increase in motor fuel consumption which goes on is destined, however, to bring about revolution and the adoption of any new thing which can safeguard the consumer against prohibitive fuel cost.

For the question stands unanswered today, just as it has for forty years, have we reached our maximum crude oil production?

The advance in prices of the fuel fractions for this season alone is sufficient to warn us for the coming consequences when we do reach the zenith. We may as well assume that we are going to reach it one of these days, and take a few forethoughts as to what actually can be done to conserve the petroleum resources. We do not at all fully appreciate the importance of our petroleum, nor are any of us prepared to say what could be found to substitute it, were it no longer available.

If we go back to the graphical triangular representation of petroleum, which, being hurriedly drawn, makes no claim to precision, but can be counted upon to represent facts as roughly and about as closely as a quick conception could state them, we will see how great is the division in favor of fuels. For, beginning with the fourth group, everything upward is consumed either to heat us, move us, or light us.

If we look at the combined sixth, seventh, and eighth groups, and consider them as adapted to gasoline motors, then consider the number and extent of these motors; and if we look at the tenth division, representing natural gas, and consider that Buffalo, Erie, Cleveland, Cincinnati, Pittsburgh, practically all the intervening area and much surrounding, represents possibly one half the natural gas consumption; that all these communities depending on natural gas have reasonable expectation of many years of service, we get a good comparative idea of space nine, which represents what is being wasted, what has always been wasted throughout the life of the crude oil industry

The Flight of Projectiles—II

The Actual Positions of a Shell from Gun to Target

By Rear-Admiral N. C. Twining, U. S. N., Chief of the Bureau of Ordnance

Reproduction of Motions.

IN 1911 the Bureau of Ordnance of the Navy Department made a small model projectile and suspended it on gimbals. The projectile was then rotated at a speed of 3,000 to 5,000 revolutions per minute (being about the speed of rotation of a large-caliber projectile). To simulate the air resistance in flight, a blast of air was directed against the rotating projectile, and the behavior of this projectile confirmed the theory in all respects. As soon as the blast of air was directed against the rotating projectile, the projectile began to precess about the direction of the air. As the blast of air was changed in direction to simulate the changing direction of the resistance in flight, the projectile's axis depressed to meet the new direction of the air blast.

A similar demonstration can be made with an ordinary gyroscope. With care in manipulation the partial precessions made by a projectile can be simulated.

Penetration of Armor.

It is evident, even to the lay mind, that if projectiles struck with their axes not in the trajectory, penetration of armor would be almost impossible. This will be evident from an inspection of sketch No. 6.

The forward part of the projectile would strike first, but as the point of the projectile is not moving in the direction of the trajectory, there would be a tremendously powerful moment forcing the projectile broadside against the armor. Practically no harm would be done to the armor, and the projectile, being forced at high velocity broadside against the armor, would be broken up.

The fact that armor has not more often been pierced in naval battles is used by those who believe the shell does not strike point on as a proof that their theory is correct. They argue that if the projectile struck point on, the armor would be pierced.

The small number of armor penetrations in naval battles is due to a number of causes.

First. The armored part of a vessel is but a small part of the whole target, and, therefore, of the relatively small number of hits that have been made in naval engagements, only a few have been made against armor.

Second. Frequently high explosive shells, with thin walls and sensitive fuses, have been used in naval battles, and these projectiles on striking armor will break up or explode without penetrating, as such projectiles are not designed for penetrating armor.

Third. Even with well-designed armor-piercing projectiles complete penetration is not likely when the projectile but slightly overmatches the armor, unless the impact is not far from normal. Projectiles striking armor at an angle of more than about 10 degrees from normal are subjected to severe cross-breaking stresses, as will be seen from sketch No. 7.

It is not expected that penetration will be secured under such conditions without the breaking up of the projectile, unless the projectile considerably overmatches the armor.

It is due mainly to the foregoing causes that armor penetrations have not been more frequent in naval battles. To demonstrate, however, that penetration will occur at battle ranges, and to further demonstrate that the projectile does travel with its axis in the trajectory, the Bureau of Ordnance of the Navy Department, in 1911, conducted a series of firings against modern 8-inch and 10-inch armor. Three hits were made at a range of 7,800 yards, one in an 8-inch plate, and two in a 10-inch plate. All three projectiles penetrated the armor, leaving clean, round holes. The evidence was conclusive not only that the projectile traveled with its axis in the trajectory, but that modern armor could successfully be penetrated at battle ranges, and that the data obtained from short-range firings at the proving grounds could be applied equally well to long-range firing.

Retardation of Velocity.

There is another proof that projectiles in flight must travel nearly point on. It is evident that the retardation of the projectile, due to resistance of the air, must be much less when the projectile is moving point on than when it is moving considerably inclined to the trajectory, as in sketch No. 2. In the latter half of this trajectory (see first article) the area on which the air pressure acts has so greatly increased over that in the first part of the trajectory that the velocity of the projectile toward the end of the range would fall off very rapidly. It is found from actual firing, however, that the retardation of velocity in the latter part of the trajectory is actually somewhat less than the retardation in the first part. This means, of course, that the projectile must travel practically point on throughout its flight. The ranges obtained from actual firings do not vary more than one or two per cent from the ranges calculated by assuming that the projectiles travel, throughout their flight, point first.

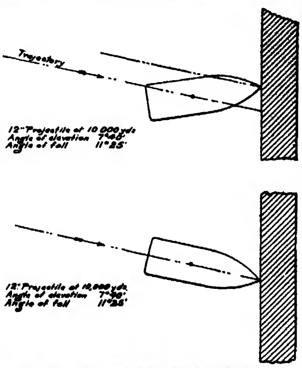
Explanation of Drift.

It is found that all projectiles having right-handed twist drift to the right. This is exactly opposite to the drift or curve of a baseball, which with a right-handed twist drifts to the left. The explanation of the left-handed drift of the baseball is simple. The air, rotating with the baseball, banks up on [illegible] against the still air to a greater degre[illegible] on the left side, and the resultant reac[illegible] against the baseball deviates the baseb[illegible] There is a similar effect occurring in pr[illegible] is very small, and the drift of projectiles [illegible] causes.

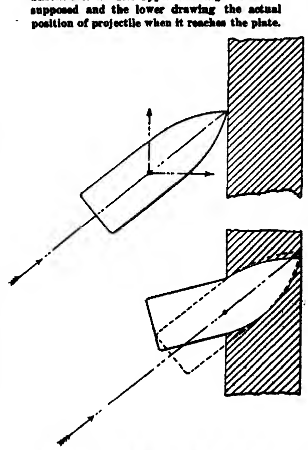
The rotating projectile is continually [illegible] tial precessions, the point of the projecti[illegible] tically always slightly to the right of the [illegible] of the trajectory. It is evident, therefo[illegible] is a small component of the air resistanc[illegible] lates the projectile to the right. This is [illegible] element in causing deviation in project[illegible] jectiles with right-handed twist drift to [illegible]

In addition, there is the effect of the fri[illegible] which assists in moving the projectile [illegible] right.

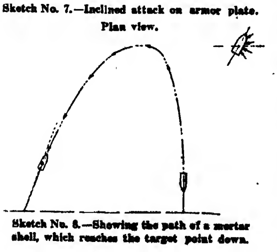
If the axis of the projectile remains p[illegible] original direction, as in sketch No. 2, it w[illegible] cult, if not impossible, to account for the [illegible] projectile. If it is maintained that the [illegible] mains parallel to its original direction, no[illegible] tional forces could give the projectile devi[illegible] these forces would decrease with the ran[illegible] quently, the rate of drift would fall off as [illegible] increased. Exactly the reverse takes place [illegible] projectiles, the drift increasing very rapidly w[illegible] crease of range. This increase of drift is occa[illegible] principally by the fact that the amplitude of the [illegible] cessions increases as the range increases; that is, [illegible] point of the projectile deviates farther from the [illegible] jectory. The resulting component of the air resista[illegible] which translates the projectile bodily to the right, [illegible] therefore stronger, and as the velocity of the proje[illegible] is being continually lessened, the drift increases rap[illegible]



Sketch No. 6.—The upper drawing shows the supposed and the lower drawing the actual position of projectile when it reaches the plate.



Sketch No. 7.—Inclined attack on armor plate. Plan view.



Sketch No. 8.—Showing the path of a mortar shell, which reaches the target point down.

High-angle Fire.

In high-angle fire it is very necessary, in order to ensure accuracy, that the projectile fall point first. As the angle of elevation increases the axis of the projectile must turn through larger and larger angles, in order to descend point first, and the greater part of this change of direction has to be made in traveling a relatively short distance near the top of the trajectory. This will be evident from an inspection of sketch No. 8.

Those who believe in sketch No. 2 would predict that all projectiles fired at high elevations would fall base first. Yet, all records and data show that these projectiles fall point first until angles of elevation of more than 70 degrees are reached. If fired at elevations exceeding 70 degrees, projectiles may fall base first, as will be clear by reference to sketch No. 8. It should be understood that the angles mentioned vary somewhat, and depend on the projectile used, its velocity, and its speed of rotation. In general, for high-angle fire a fairly low rotation is used (1,500 to 4,000 revolutions per minute), in order that the projectile may respond quickly and fall point first. As low velocities are used for high-angle fire, a low speed of rotation will ensure stability. It can readily be seen from sketch No. 8 that if a projectile has a high speed of rotation, and, consequently, a precession of slow rate, and small amplitude, there will be a definite angle of elevation for that projectile, such that when the projectile reaches the top of its trajectory the direction of the air resistance will change faster than the tendency of the point to follow. It should be borne in mind that owing to the low velocity of the projectile at the top of its trajectory, the gyroscopic moment is very small, even although the lever arm increases rapidly with the change of direction of the air resistance. The gyroscopic moment being relatively small, the projectile changes the direction of its axis very slowly. As the point of the projectile dips and tends to follow the rapidly-changing direction of the air resistance, it lags behind in this movement. There soon comes a time when the direction of the air resistance is broadside to the projectile and directly through the center of gravity. At this point the projectile has no tendency to precess, and travels broadside through the air, the precession practically vanishing. As the projectile approaches the descending branch of the trajectory the air resistance falls below the center of gravity. The direction of the air resistance is now upward, and the point of application of this resistance is in the lower part of the projectile. This tends to start a precession of the projectile with the base of the projectile precessing around the air resistance. That is, the base of the projectile tends to come over to meet the line of the air resistance, and thereafter the projectile falls base first. The angle of

elevation beyond which the projectile falls base first is reached sooner in proportion as the speed of rotation is increased, the projectile shortened, and the velocity decreased.

In May, 1912, five 12-inch projectiles were fired from United States Army mortars at an angle of elevation of 65 degrees. The observing party consisted of four officers and three enlisted men. All five projectiles were seen in the descending branch of the trajectory, falling point down. The results of this firing confirmed those previously obtained from similar firings.

Satisfactory firing has also been obtained at angles as great as 70 degrees, though it is found that the drift of the projectile is likely to be irregular at this elevation.

The angle of elevation which decides whether the projectile will fall point first, or base first, depends to such an extent on the variables previously mentioned that it is not possible to state more than that for the conditions under which mortars are fired the angle is probably not much greater than 70 degrees. Mortar fire is usually limited to angles of elevation of 65 degrees.

Authorities.

A large number of scientific authorities might be quoted, all of whom are believers in sketch No. 1. The eminent German authority, Prof. Cranz, and the eminent British authorities, Prof. Greenhill and Prof. Henderson, have demonstrated that the axis of a projectile remains sensibly tangent to its trajectory. Brig.-Gen. William Crozier, Chief of the Ordnance Department of the U. S. Army, also maintains the correctness of sketch No. 1. There is not an authority in any country who maintains the correctness of sketch No. 2.

It should be understood that the foregoing discussion of the flight of projectiles is complete only in so far as pertains to the object of this article. No mention has been made of the nutations described by the point of the projectile, or of the motions occasioned by forces impressed on the projectile on leaving the gun. There is much information that could be given on the action of the air resistance, the effects of various riflings, etc., but none of these have more than an indirect bearing on the subject, and do not change in any way the deductions in this article.

It is believed that the credence given to sketch No. 2 has been due wholly to popular misconception, and it is hoped that sufficient data have been presented in this article satisfactorily to establish the fact that a rotating projectile in flight must have its axis at all times sensibly tangent to the trajectory.

High Temperatures and the Electric Furnace

The Different Types of Electric Furnaces

By Prof. Joseph W. Richards, Lehigh University

WITHIN the last twenty years, electrically-generated heat has been a favorite topic of discussion among chemists and metallurgists, and the possibilities of using it industrially are attracting great attention. Various types of electric furnaces have been devised and put in operation, for such various purposes as producing pig iron, melting steel, melting brass and bronze, making silicon carbide, calcium carbide, titanium carbide, converting ordinary carbon into graphite, melting quartz, fusing glass, reducing tin ores, melting gold and silver precipitates, converting nitrogen and oxygen in the air into nitric acid. In fact, the uses of electric furnaces have become so various that a large-sized book can easily be written about it, and several such are already in print in the German, French and English languages. Any bookseller, or importer of French or German books, can furnish this literature to any one interested in it.

There are various types of electric furnaces, adapted to different kinds of service. For some purposes extremely high temperatures are necessary, and for these the electric furnace is indispensable, since the result desired cannot be obtained in any other kind of furnace. The highest temperatures attainable by combustion of solid or gaseous fuel, with pre-heated air, approximate 1,500 to 2,000 deg. Cent. (2,700 to 3,600 deg. Fahr.), and it takes a large consumption of fuel and there is a large waste of heat in attaining such temperatures on an industrial scale. The electric furnace, however, is limited in temperature only by the resistance of the material with which the furnace is lined, and the volatilizing temperature of the carbon electrodes used for carrying current into the furnace. The latter temperature approximates 3,700 deg. Cent. (6,700 deg. Fahr.), which is above the melting point of any ordinary material with which a furnace can be lined, excepting carbon. The ordinary refractory materials used in furnaces burning fuel melt at a temperature between 1,500 and 2,000 deg. Cent. (2,700 to 3,600 deg. Fahr.), and carbon is practically the only material which will stand the higher temperatures attainable in an electrical furnace.

It must not be supposed, however, that the electric furnace necessarily must be run only for the attainment of very high temperatures. Some of the most successful electric furnaces, operated where electric power is cheap and fuel is relatively dear, are operated at temperatures no higher than are obtained in ordinary non-electrical furnaces. The electric current is in this respect somewhat like a race-horse which is capable of running at high speed (high temperature) and yet which can be loaded down so as to work at low speed upon heavy loads (low temperatures). In fact, the ordinary electric oven or the toaster used in our houses is on the principle of an electric furnace, but operates at very moderate temperatures.

Arc Furnaces.

Such furnaces are simply enormous electric furnaces, on the same principle as an electric arc used for lighting, excepting that they are surrounded, as completely as possible by the material to be heated, and the heat radiated from the arc is utilized for purposes of fusion, chemical reaction, etc. The maximum temperature close to the arc may be as high as 3,700 deg. Cent. (6,700 deg. Fahr.), but the material surrounding the arc is not by any means necessarily heated to this extreme temperature. The charge receives the radiated heat and is carried to as high a temperature as the amount of heat radiated from the arc can heat the substance. If the substance is small in amount and brought nearly in contact with the arc, it may be heated nearly to the very high temperature named; but if the arc is surrounded by a large mass of the substance under treatment, then the material is heated only to the average temperature to which the electric energy converted into heat in the arc is capable of heating this large mass of material; this temperature may be almost anything, down to ordinary low furnace temperatures.

Illustrations of the use of the arc furnace are the Stassano furnace for melting steel, the DeLaval furnace for smelting zinc ores, the calcium carbide furnace, the ferro-silicon furnace, the furnace for fixing atmospheric nitrogen and thus producing nitric acid from the air. These furnaces work with the material heated from 1,500 deg. Cent. (2,700 deg. Fahr.) to 3,000 deg. Cent. (5,400 deg. Fahr.). Their chemical possibilities depend upon either one of two things, first, that materials for reactions are produced in them not producible in furnaces run by fuel (nitric acid, calcium carbide, ferro-silicon), or, second, that they are cheaper to apply than ordinary furnaces (smelting zinc ores and melting steel, in Sweden or Norway).

I have mentioned some of the more common applications of these enormous arc furnaces, but many others are under experiment and will undoubtedly be developed in the future. Their real and proper field is for carrying on operations at high temperatures not obtainable by other and non-electric means.

Resistance Furnaces.

This type of furnace passes the electric current continuously through some material offering resistance, and generates therein the high temperature required. There is no arc or break in the electric circuit; these furnaces are run simply on the hot-wire principle—a conductor is heated by the passage of an electric current, and sufficient current is sent through a particularly designed resistor to generate the heat and temperature necessary for running the furnace.

This is a large, useful and important class of furnaces, which is entering into many industrial operations. They are preferably operated by alternating current, although this must be of low voltage for most resistance furnaces. Examples are numerous; one of the simplest is the furnace of Mr. Acheson in which several tons of ordinary anthracite coal is converted into graphite by the passage of the electric current through the coal itself, thus heating it (properly shielded from the entrance of air) to a temperature of at least 3,000 deg. Cent. (5,400 deg. Fahr.) during a period of about twenty-four hours and converting it into soft unctuous graphite of many times the value of the material put in the furnace. Another example is the mixing of ordinary silica sand with coke and saw dust, and passing an electric current through a heap of the material piled between electrode terminals twenty to thirty feet apart. With a voltage of 100 to 200, and a current of over 1,000 horse-power, the electric current generates within the mass a temperature sufficient to form from these ingredients the well-known material "Carborundum," which is formed at a working temperature of 2,240 deg. Cent. (4,000 deg. Fahr.). Large industries have been founded upon the invention and use of these electric furnaces, so simple in principle and yet which require the highest inventive skill and industrial pertinacity to devise and operate successfully.

Induction Furnaces.

These are really a special kind of resistance furnace, the material or resistor being heated by the passage of an electric current, but not by the current originally sent to the furnace. The furnace itself is an electric transformer, receiving high-voltage alternating electric current, and transforming it to low-voltage current of great quantity, and the induced or secondary current of the transformer is the heating current which passes through the resistor and doing the useful furnace work.

A reference to the ordinary transformer with which almost every one is familiar may make the matter clearer. Electric current is sent along many of our thoroughfares at 2,000 volts tension, a current which would be very dangerous if it entered our houses, but which is transformed at convenient stations into low-tension current for safe use. The apparatus accomplishing this is called a transformer, the original current passing through the primary winding of the transformer, while the useful current is taken away from the secondary winding. The induction electric furnace operates on exactly the same principle; it has a primary winding receiving the high tension electric current but its secondary winding is the material itself which is to be heated, arranged in a closed circuit, so that all the energy of the secondary electric current is utilized as it is generated in the furnace itself.

Electric Furnaces.

These last are in reality not primarily furnaces; they are furnaces only *incidentally*. If we electrolytically decompose a liquid by passing a direct current through it, the operation is electrolysis. Such operations are familiar to every one: Gold, silver and nickel-plating baths; electrolytic refining of copper, silver, gold, lead; electrotyping; electro-engraving; reproducing coins, medals, etc. Others less well known are the obtaining of metallic sodium from fused caustic soda, of calcium from melted calcium chloride, of aluminium from a fused bath containing fluoride of aluminium and sodium with alumina (aluminium oxide) dissolved in it. Now, when these fused baths are kept melted by the heating effect of the passage of the electrolyzing current itself, the apparatus is called an electrolytic furnace. It is, therefore, a pot primarily run for electrolysis, whose necessary temperature may be maintained by externally-applied heat (as by building a fire around the pot); but when this necessary temperature is maintained by the internally-generated electric heat, the result is not simply an electrolytic cell, but an electrolytic furnace. The amount of heat generated by the current depends on the strength of current and the distance of the electrodes apart; it can be regulated with exactness to that required to supply radiation losses and keep the contents at the proper working temperature. Sir Humphry Davy was the first to experimentally use this principle, Mr. Charles M. Bradley of New York patented the electrolytic furnace, and Mr. Charles M. Hall was the first to practically run electrolytic furnaces in the production of aluminium.

These types of furnaces, with others possibly still to be invented, are revolutionizing many branches of industrial chemistry and metallurgy, and are founding or establishing many new ones. They deserve serious and intelligent attention.

The German Observatory in Spitzbergen, which was established by Prof. Hergesell partly with a view to determining the meteorological conditions that will be encountered by the projected expedition of Count Zeppelin *via* airship to the North Pole, has completed a full year's work with such fruitful results that it has been decided to keep the institution in operation another year. The two observers, Drs. Rempp and Wagner, have been relieved by Dr. Kurt Wegener, lately in charge of the Samoa Observatory, and Dr. Robitzsch. During last winter a series of aerological observations was carried out with kites, pilot balloons, captive balloons, and sounding balloons, yielding a unique body of information concerning the winter conditions in the upper air of the Arctic regions. Valuable contributions to the climatology of Spitzbergen were made through the maintenance of three meteorological stations at different altitudes; the highest on Mount Nordenskjöld (3,360 feet). Unbroken series of magnetic and seismological observations were also made.

WE announce for 1913 big improvements in Chalmers cars in *comfort, convenience* and *appearance*. For it is along these lines that we believe the greatest advances in automobile building are to be made.

Few changes have been made in our chasses. The mechanical features of our cars have been right from the beginning. Satisfactory service in the hands of 27,000 owners proves this.

Here, then, are the principal additions and improvements on Chalmers 1913 cars:

Easier Riding Qualities

Luxurious comfort is built into every detail of Chalmers cars. The Turkish cushions, 11 inches thick, are soft as a down pillow. They are the highest grade automobile cushions made.

The upholstery is of the luxurious overstuffed type. All seats are wide, filled with high grade hair and covered with heavy, soft, pebble-grained leather. A Chalmers car gives you the same restful comfort as a big armchair.

The long wheel base minimizes road shocks. Big wheels and tires, and long elastic springs make all roads smooth. You can ride all day in a Chalmers without fatigue.

More Conveniences for Operator

Electric Lighting, the last touch of luxury, is regular equipment for 1913 on the "Thirty-Six" and the "Six." The Gray & Davis system which we use is featured on some of the highest priced cars; we believe it is the best lighting system built.

Just touch a switch on the dash and you can light at will head, tail, and side lights. No hunting for matches or gas tank key. No getting out of car in dust or mud.

And no more cranking. The Chalmers air pressure starter made 1912 a self-starter year. A season's use has proved this the simplest and most efficient starting device yet designed. You simply press a foot button on the dash and compressed air, released from a tank beneath the car, turns the motor over until it starts on its own power. No danger. No strain on motor.

Continental demountable rims reduce tire trouble to the minimum. Occasional punctures you *may* have are no longer a serious inconvenience. With demountable rims you can change tires in a few minutes.

On the new style Chalmers dash is carried every control and indicator—ignition switch, self-starter button, electric light switch, speedometer, gasoline pressure pump, carburetor adjustment, air gauge, oil sight feed, priming lever, horn bulb—all easy to see and easy to reach.

Added Beauty

Chalmers cars have always been known for their "looks." For 1913, they are even more beautiful than in the past. Flush-sided metal bodies have the graceful bell-shaped back. Dash is of one piece with body. Top of hood and sides of body form one line from radiator to rear seat.

Handsome nickel trimmings will be regular equipment. Leather lining throughout the body and on the dash leaves nothing to scratch or mar. Twenty-one coats of paint and varnish give a finish that cannot be surpassed.

We have perfected Chalmers cars along these lines, we believe, to a greater extent than any-one else, because for the last ten months we have directed all our efforts to making our cars even more *comfortable*, more *convenient* and more *beautiful* than ever before.

The Chalmers "Six," $2400 —A Maximum Car

Quantity production and increased manufacturing facilities make possible this unprecedented price of $2400. Here is a tried and proved six-cylinder car of the finest quality—of Chalmers quality—the first thoroughly high-grade six-cylinder car at a moderate price.

We are proud of this car. No automobile can give you more service, more enjoyment, more satisfaction and pride of ownership than the Chalmers "Six."

In addition to the big features of Comfort, Convenience and Beauty listed above, please note the following:

Power Enough For Anyone

The "Six" motor is a giant of power. Though rated at 54 h. p., it actually develops 60 to 70 h. p. The long stroke motor—4⅛" bore x 5¼" stroke—gives it a strong "pull" in sand or mud or on the steepest hill. It can be throttled down to a walking pace on high gear. It picks up instantly. An ideal motor for every requirement—mile-a-minute speed, slow running in city traffic, hill climbing, or dogged ploughing through sand or mud.

18 Notable Features of Chalmers Cars for 1913

Electric Lights	Increased Wheelbase	Jewelled Magnetic Speedometer
Turkish Cushions	Improved Springs	4-Forward Speed Transmission
Eleven-inch Upholstery	Chalmers Self-starter	Big Wheels and Tires
Nickel Trimmings	Long Stroke Motor	Dual Ignition System
New Flush-sided Bodies	Demountable Rims	Carburetor Dash Adjustment
Special Silk Mohair Top	Cellular Radiator	Rain Vision Windshield

The Utmost Flexibility

Chalmers four-forward speed transmission provides a gear for every requirement. It enables you always to select the gear that will carry your car through any kind of going in the quickest time and with the least strain.

Big wheels and tires.—36" x 4½"—insure easy riding and cut down tire trouble and expense.

Control levers inside the body; pedals for clutch and brake conveniently located; improved accelerator which does not tire the foot; gasoline shut-off valve inside the tonneau; exceptional oiling facilities; controls on dash within easy reach—make the "Six" a delightful car to drive.

You Feel Safe in Your Chalmers

The most careful attention has been given by Chalmers engineers to the *factors of safety*. Wheels are unusually sturdy. Axles are built in our own factory, of the highest grade steels. Double drop frames are heavy and of finest heat treated steel. Brakes are extra large in proportion to the weight. Steering gear is of new Chalmers design, with extra heavy drop forged connections—none stronger or easier to operate.

Even to the smallest details, the "Six" is a maximum car. Door locks are concealed and equally accessible from inside and outside. Bodies are thoroughly ventilated. All parts of the car are unusually accessible.

The "Thirty-Six," $1950— With Fine New Features

Striking improvements and added features make the 1913 "Thirty-Six" more than ever an ideal all-around motor car. It has power in abundance, speed, hill-climbing ability and rugged endurance to meet the utmost demands.

First offered to buyers last year, this car has proved the most popular ever sold at the price. Many refinements and improvements for 1913 give even greater smoothness, quietness, comfort and convenience. For style and good looks it is not surpassed.

The wheel base of the 1913 "Thirty-Six" has been increased to 118 inches, which still further improves its easy riding qualities.

Luxurious Turkish cushions, 11-inch upholstery (the same quality as used on some $5000 cars), tilted seats, all give the greatest possible riding ease. Seats are exceptionally roomy.

Big 36" x 4" tires carry the car smoothly over the roughest roads. The "Thirty-Six" is over-tired, which means less tire expense. Springs are unusually flexible.

Electric Lights on These Cars

Full electric lighting by the Gray & Davis system is furnished on the "Thirty-Six."

Chalmers self-starter, simplified and improved, is furnished on the "Thirty-Six" of course.

A reliable Speedometer, a jewelled, magnetic instrument, is regular equipment.

1913 bodies are greatly improved in design and finish. They have the integral cowled dash, on which are carried all controls. Everything for the handling of the car is within easy reach.

Note the wide doors, smooth straight sides, rounded back, graceful cowled dash, elegant appointments.

The "Thirty-Six" has even more graceful lines than last year. The painting is of the highest quality.

Mechanically Correct

This car will do your work with *power to spare*. The splendid long stroke motor—4¼" x 5½"—has wonderful pulling qualities. Quiet and smooth running at all speeds.

The four-forward speed transmission is one of the distinctive Chalmers features largely responsible for the success of the "Thirty-Six" last year.

Other Chalmers features which made this car such a marked success are retained—such as dual ignition, demountable rims (five), genuine honeycomb radiator, dash adjustment for carburetor, large brakes, frame and steering connections of extra weight and strength.

The 1913 Chalmers "Thirty-Six" offers you every motor luxury—at a medium price.

Chalmers Motor Company, Detroit

The New Chalmers "30"— Self-Starting, $1600

With improved motor, Chalmers self-starter, 34"x4" tires, demountable rims, larger brakes, beautiful, new flush-sided body, the 1913 "30" at $1600 is a greater value than ever before.

The price includes also gas lamps and oil lamps, Prest-O-Lite tank, dual ignition, full tool equipment.

For the man who wants a light, fast, low priced, but classy car, the 1913 "30" is the best buy ever offered.

The Chalmers "30" has for five seasons set the standard of values among medium priced cars of this power. It has won more endurance contests, broken more records, been victor in more races than any other car of its size and power. And it has a wonderful record of steady service and satisfaction in the hands of owners everywhere.

Two body types are offered: 5-passenger touring car, $1600; 4-passenger torpedo, $1600.

Fixed Chalmers Policy— Quality Cars at Medium Prices

For 1913 we are adhering to our established policy of always giving the greatest possible value for the price. We have incorporated in our new model, at medium prices, all of the features of higher priced cars and many features not found on other cars of any price.

Chalmers cars have always been known as quality cars. We have never built a "cheap" car, but always high quality cars at medium prices. Big production has enabled us to build such cars at lower cost than could anyone without our volume. We have never tried to secure big volume, however, at the expense of quality or advanced features. Yet each year the extraordinary values in our cars have brought a steady natural increase.

1912 Our Record Year

This past year, 1912, was the best year we ever had. It set a new Chalmers record. Our business showed an increase of 43% over the season of 1911.

We believe that our business will further increase as people appreciate quality at medium price instead of *quality* at *high* prices or mere *quantity* at *low* prices.

We believe the more automobiles come into use, the greater will be the conviction that it doesn't pay to try to save $300 to $500 on the original price, and buy something merely because it is offered at a low price.

Medium priced cars of quality—not only ours, but other good medium priced cars—offer the best values for the money in the long run, and you don't have to run them very long to find it out.

Built in Our Own Shops

Chalmers cars are built by Chalmers workmen in Chalmers shops under Chalmers inspection. We build our motors, transmissions, axles, self-starter, steering gear, and other important parts. We cut our own gears, heat-treat our steels. We even have our own foundry.

No automobile manufacturer builds in his own plant more of the parts of his car than we do. No motor car factory is more completely equipped with new machinery.

Experts tell us no car is built with greater care or more skillful workmanship than the Chalmers; none is subjected to more careful and painstaking inspection.

Backed by Sound Guarantee

Chalmers cars are built and guaranteed by a company of the soundest financial standing. We have a plant covering 30 acres of ground and have $6,000,000 invested in our business. We have made this great investment because we expect to be in this business permanently, and we are convinced that permanent business can only be built up where a manufacturer makes his own parts.

Making our own parts means greater accuracy in our cars and greater value for you. The saving we make by eliminating parts-makers' profits, goes into added quality.

We have prepared a book about the Chalmers factory. It tells, in an unusually interesting way, how Chalmers cars are made. Write for it on the coupon attached.

Order Now For Early Delivery

Now is the time to order so that you can get the use of your car during the best motoring season.

So see these cars at our dealers' showrooms. If you look them over carefully, we are sure the cars will more than bear out our every claim. Again we say, compare them with other cars—point by point—price by price—value by value. Your verdict is sure to be favorable.

And don't forget to send the coupon for the booklet "Story of the Chalmers Car," and our new catalog. You will find this book about the making of an automobile both entertaining and worth while, no matter what car you decide to buy. Just mail the coupon today.

Please send "Story of the Chalmers Car" and complete information regarding the Chalmers 1913 cars.

Track Laying by Machinery

THE modern track laying machine should not be confused with track laying tools, as this machine is not a tool, but a real machine that actually lays tracks as indicated in the accompanying photograph. The machine moves steadily forward over the track it lays at a rate of from twelve to forty feet per minute. At the rear of the track laying machine are cars loaded with ties and rails. The cars which carry the ties are in advance of those carrying the rails. The rails are drawn forward on rollers and are connected temporarily one to the other. As the rails pass under the cars which carry the ties the latter are distributed upon the rails and spaced apart uniformly. The chain of rails thus serves to transport the ties toward the track laying machine. As the rails enter the machine, the ties are picked up by a conveyor and carried overhead. They are distributed on the roadbed at the end of a truss that reaches far in advance of the main body of the truck laying machine. The rails in the meantime are carried forward and deposited upon ties previously laid. The truss may be swung to one side or the other in order to allow for passing around curves. The track laying machine is self-propelling. It hauls a train of twenty-five cars of material, more or less depending upon the grade. A train of twelve cars will carry enough material for a mile of track. This machine, with eighteen men, including spikers, can lay and bolt and spike a half a mile of track per day. With a larger force of men two miles of track may be laid in a single day.

The Wreck of the "Schwaben"

AFTER making a total of 384 flights, in which it covered 28,000 miles and carried 6,045 passengers, the "Schwaben," the first of the huge Zeppelin airships to make regular passenger trips, came to grief on June 28th while anchored outside of the obsolete shed at Dusseldorf in a heavy wind. So much did the airship bob about in the maelstrom that Capt. Duerr decided to go aloft and ride out the gale. He was just about to cast off the mooring cable at the bow when the nose of the ship burst into flame, and he and his crew jumped for their lives. The flame soon ran the entire length of the airship, and she was consumed as she swung at anchor, the fall to the ground breaking her back, as shown in the photograph. The cause of the catching fire of the "Schwaben" in this mysterious manner is thought to be the working of her frame at the bow, where she was tethered. This is believed to have generated frictional electricity sufficient to have ignited the gas. That the cloth covering of the dirigible also had something to do with the generation of this frictional electricity is shown from the fact that the Zeppelin engineers are perfecting a "neutralized" cloth that cannot be electrified. The airship was insured for $162,000. She had made for her owners her entire cost of construction and operating expenses by carrying passengers. The latest Zeppelin, "Hansa," has shown a speed of 49 miles an hour, and the new naval one now building, with 600 horse-power, is expected to travel 60.

An Earth-driven Clock

IN the ordinary clocks provided with weights and springs, the clock mechanism drives the pendulum. In the clock pictured herewith, however, the operation is reversed for the pendulum drives the clock. The pendulum receives its energy from an electro-magnet supplied with current from an earth battery. Because the earth currents are apt to vary considerably, a special automatic switch mechanism is provided to check the pendulum when it swings too far. Thus, a constant amplitude of oscillation is maintained. The pendulum is provided with a bob, consisting of a coil of insulated copper wire, inclosed in a brass case, underneath which there is a similar bob for making the necessary initial adjustment. The terminal wires from the bob coil are carried to the top of the pendulum where they connect to two springs on which the rod is suspended, and then make connection with the earth battery. A permanent steel magnet is mounted on the clock case, adjacent to the bob coil. The poles of the magnet enter tubular openings at each end of the coil. Hence, when current flows through the magnet, there is either an attraction or a repulsion, according to the direction in which the current passes around the coil.

The direction of flow is alternated by a contact gear, which is attached to the pendulum rod. It consists of a small carrier mounted on two wheels that run over a track, secured to the clock case. The wheels run over contacts placed in the battery circuit. The carrier is set in motion by two adjustable contact rods on the pendulum, which push it forward or backward, depending upon the travel of the pendulum at the time. Thus alternate impulses are produced in the coil, which serve to keep the pendulum in motion. To oppose an abnormal swing, the contact pieces are arranged in three parts, so that if the pendulum moves the carriage too far, its wheels make contact with the third members of the contact group and this reverses the current. Recently Prof. Silvanus P. Thompson subjected the clock to a number of tests. In his report he states that if he purposely gave the pendulum a large impulse so that it swung too far, the automatic action of the contact device became evident at once, and after a few swings, the pendulum returned to its normal swing.

A Machine That Enables Coal to Be Pumped

NO industry is more prolific of disaster, both distressful and costly, than coal mining, and no other industry of this country, owing to the crude methods employed, imposes such hardships upon the workman immediately engaged in taking coal from the vein. To alleviate these dangerous conditions J. H. Hoadley and W. H. Knight have developed a system of mining coal by machinery.

Primarily designed to cut the whole seam of coal into a granular state suitable for coking, this coal-milling machine may modify the art not only of mining coal, but of transporting and consuming it. It is well known that granular or powdered coal, with the aid of water, can be pumped through pipes at far less cost than it can be transported by rail. It is also certain that powdered coal, when blown into a furnace with an air blast, burns with much more economy than does lump coal when burned on the grate.

There are, however, 100,000,000 tons of coal coked each year in this country, and it is with especial reference to this kind of coal that the inventors have directed their attention.

The milling machine not only cuts the coal from floor to roof into a finely powdered state, but pumps it, mixed with water of the mine, to a distant coal washer or to coal bins adjacent to the coke ovens. It necessarily does away with the use of explosives, and with the coal dust. The system is a peculiarly safe one to use in gaseous mines on this account.

The machine itself is automatic, advancing by a simple hydraulic feed mechanism which propels it along the floor into the face of the seam, the rotary cutters on the armature shaft of the induction motor cutting the coal very much as a circular saw cuts wood. The motor is given, in addition to its forward movement, a sidewise swinging motion through a limited angle so that the proper width may be cut. Any partings are, of course, comminuted at the same time as the coal, and are separated afterward in the washing process. A fire engine hose leading from some source of water under pressure enables a powerful stream of water to be thrown against the face of the coal while it is being cut, thus eliminating all dust and keeping the tools cold. The water carries off the comminuted product to the nearest sump, whence it is pumped to any desired destination. The machine, owing to its power of advancing directly into the coal, will cut a slope, an entry, a room, or work along the wall.

Trade-mark as a Business Asset

By W. E. Woodward

THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer; that it is a symbol of good will, a tangible asset with a determinable money value; that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.

The following is the sixth of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

Analysis of the Requirements for Registration.—VI.

(Continued from page 121, August 10th, 1912.)

The U. S. Sanitary Manufacturing Company was refused registration for a trade-mark consisting of the letters "U. S." with a background of a shield similar to that of the conventional United States shield. The coat of arms for the United States is not registrable as a trade-mark even under the ten years' clause. It has been held that its use in that connection is opposed to public policy. (American Glue Company, ex parte, 120 *Official Gazette*, 324.) The registration of the coat of arms of the State of Maryland was refused registration, application having been made under the ten-years' clause. In another case, registration of a simulation of the shield of the United States, with alternate red and white stripes, was refused registration.

It would seem at first consideration that if the object of using a trade-mark is to indicate the origin of a commodity, the most effective marks would be simply the maker's name—"James Brown" for goods made by James Brown, and "William Jones" for goods made by William Jones. This logic would be indisputable if there was a different family name for every individual. But names are limited in number—there are eleven pages of Smiths in the New York city directory—and every man has a natural and inalienable right to use his own name. But a personal name may be written, or printed, or stamped in such a way that the peculiarities of writing, or printing, or design, may dominate the name and be the most conspicuous feature of the combination.

The trade-mark act provides that "no mark (shall be registered) which consists merely in the name of an individual, firm, corporation, or association, not written, impressed or woven in some particular or distinctive manner, or in association with a portrait of the individual." In this clause the framers of the act have endeavored to put a logical restriction on the injudicious use of personal names as trade-marks and the endless litigation that has always resulted from this practice.

The names of historical personages (not living) may be registered as trade-marks, but the name of a living person cannot be used without his consent. The phrase "Gibson Girl," as a mark for shoes, was refused registration, as the word "Gibson" obviously referred to Charles Dana Gibson, a living artist. In case of the registration of the names of individuals, firms or corporations, the restriction of the law that the name must be shown in some "particular or distinctive manner" has been interpreted to mean a presentation of the name in such a form that the peculiarities of lettering, or writing, or of an accompanying device are so pronounced that they dominate the name and throw it into a position of secondary importance. The meaning of this clause is best shown by means of examples of proper names, registered and used as trade-marks.

Many portraits of living persons are used as trade-marks, notable among them being the face of W. L. Douglas, shoe manufacturer, and the portrait of Thomas A. Edison, used in connection with his facsimile signature, as a trade-mark for Edison phonographs. Among historical characters, the picture and signature of Robert Burns, the poet, are combined in a trade-mark for cigars; the face of Benjamin Franklin is used as a trade-mark for the *Saturday Evening Post*, and will be found printed on the editorial page of each issue; Bismarck is a name for collars; Napoleon is used in connection with a brand of flour, and "Bob" Ingersoll is the trade-mark of a cigar.

It is a definite principle of the common law that fraud vitiates any transaction that it touches. A trade-mark that is deceptive and misleading cannot be protected, no matter if its registration should be accomplished. "Knights of Labor" was refused registration as a trade-mark for whiskey as the evident intent of the mark was to mislead purchasers into a belief that the whiskey was produced by the Knights of Labor, a labor organization. A similar case is exhibited in the attempt to register the name "Masonic" as a mark for cigars. Registration was refused. The name "Malt Myrrh" was refused registration as trade-mark for malt liquors when it was shown that the liquors did not contain myrrh. The name "Old Country Soap," used in connection with soap in such a way as to lead purchasers to believe that the soap was manufactured in Europe, was held by the court in the case of Wrisley v. Iowa Soap Company, to be deceptive, and protection against infringement was refused.

A false representation on a trade-mark to the effect that the article is patented, when it is not, is sufficient to vitiate the trade-mark. A trade-mark registration does not protect when it is used on an article different in character, or composition, or origin, from that for which it was registered. This principle is very important. A manufacturer cannot do as he pleases with his trade-mark without regard to the rights of the public. If the article for which it was registered is changed essentially in composition, or in purpose, the trade-mark ceases to be of value. Trade-marks under the United States law are always specific and associated with a certain definite article, and not with the proprietor's general business. In Great Britain and Canada there are general trade-marks, which the manufacturer may use on any article he makes, no matter to what diverse classes these articles belong.

A trade-mark which is technically a valid mark, will be refused registration if, in the opinion of the Patent Office, its registration would be opposed to public policy. A few examples will show what we mean. The phrase "Ask the Revenue Officer" was rejected as a mark for whiskey. The Patent Office held that this mark, appearing on bottles or barrels, would lead the public to believe that the contents had the endorsement of officers of the government. For similar reason the word "Government" was refused registration as a mark for loose-leaf binders. The name of a living ex-President cannot be registered without his written consent (as in the case of any other living person), and the name of an ex-President not living cannot be registered at all. The use of the name of an ex-President as a trade-mark is not considered consonant with the high dignity of the presidential office. Several applications have been made within the last few years for registration of the names or portraits of ex-Presidents. The signature and portrait of Thomas Jefferson, combined in a trade-mark for cigars, was refused registration. The words "Roosevelt Rose" were rejected on application for registration, the rejection being partly because "Rose" had been registered on a previous application, and partly because Roosevelt is a living person.

A trade-mark cannot be a color, because the number of colors is limited, and it would be manifestly unfair to give the exclusive use of a color to any individual.

The use of the flag or coat of arms of any foreign power is prohibited as a trade-mark. This restriction holds even when the foreign power agrees to the use of its insignia. The Russian Government consented to the use of its coat of arms as a trade-mark in the case of an applicant before the United States Patent Office, but registration was refused. The law is mandatory, and is not affected by agreement.

Any design or picture which has been adopted by a fraternal society as its emblem is not registrable as a trade-mark. For obvious reasons, scandalous or immoral matter is refused registration. A trade-mark cannot be a shape, or a package, or a container. A trade-mark cannot be the article of merchandise itself, for the "mark" must necessarily be different from the thing marked.

Proposed Amendment to the Trade-mark Law.

An amendment to the Act of 1905 is before Congress. This amendment, which will, in all probability, become a law, denies the right of anyone to register as a trade-mark any mark which consists of "any name, distinguishing mark, character, emblem, colors, flag or banner, adopted by any institution, organization, club or society which was incorporated in any State in the United States prior to the date of the adoption and use by the applicant." This proposed addition to the law is the result of an attempt of certain manufacturers to capitalize the prestige of various well-known clubs and other organizations. A case in point was a recent attempt to register the initials "Y. M. C. A." as a trade-mark. Another flagrant case was the adoption of the emblem of the New York Athletic Club—a winged foot—as a trade-mark by a manufacturer of men's clothing. On formal protest by the New York Athletic Club, the registration of this mark was held up.

The Trade-mark Status of Patented Articles.

A patent may be defined as an exclusive monopoly in the manufacture and sale of a new and useful invention granted by law for a term of years to the inventor. As an offset to this monopoly, granted to the inventor as his reward from the public, the inventor's exclusive right ceases at the expiration of the patent, and any one may manufacture and sell the invention.

It would be manifestly unfair to the public if the owner of the patent could, at its expiration, still retain the exclusive right to use the name and trade-mark under which the invention has been sold. If this were permitted, the effect would be a partial continuance of the monopoly. The name and trade-mark belong to the article—not to the individual—and the right to use them goes with the right to manufacture the article.

The Singer Manufacturing Company, when the patents on its sewing machine were about to expire, adopted as a trade-mark the word "Singer" blended with a device. The effect of this action, if the validity of the trade-mark had been sustained, would have been to perpetuate the right to the exclusive use of the word "Singer" as applied to sewing machines. In this event, at the expiration of the patents, any person would have the right to manufacture Singer machines, but only the Singer Manufacturing Company would have had the use of the name "Singer." It was held by the courts that the right to use the name "Singer," as applied to machines of this particular design, became public property when the patents expired. The court said, in the case of Brill v. Singer Manufacturing Company (41 Ohio Stat.):

> "A patentee or his assignee, by incorporating into his trade-mark the distinctive name by which a patented machine has become known to the public during the existence of the patent, cannot, after the expiration of the patent take away from the public the right of using such name. The trade-mark cannot be made a guise for extending the monopoly, or preventing the name from becoming, with the patent, the property of the public."

The Singer case is typical of cases of this character. In the case of Dover Stamping Company v. Fellows (163 Mass 191, 194, 196) the court said

> "When one who has a patented article gives to it and puts upon it a name, and calls it by that name and no other, and it becomes known to the trade and to the public exclusively by the name so given to it by the patentee or person controlling the patent, then certainly it may be said that, as a general rule the right to the exclusive use of the name ceases with the termination of the exclusive right to make and sell the thing."

(To be continued.)

Notes for Inventors

A New Patent Office Publication.—The United States Patent Office has issued a volume of nearly 500 pages, being a supplement to the manual of classification and termed "Definitions of Revised Classes and Subclasses of Subjects of Inventions." The purpose of the publication is to explain what is comprehended within the title of the subclasses established by the Patent Office and it will prove a valuable aid to the practitioners before the Patent Office.

An Anti-skid Improvement.—Rikichi Himeno of New York city, has patented, No. 1,030,238, an anti-skid device which includes two side chains to extend alongside the wheel tire and cross chains connecting the side chains at intervals. One of the side chains is separable at a point intermediate its length to divide it into two sections and means are provided for connecting and disconnecting its intermediate separated ends, the ends of both side chains being provided with means for connecting the same.

Another Peter Cooper Hewitt Lamp.—Peter Cooper Hewitt has secured another patent, No. 1,030,178, for a mercury vapor lamp in which is provided a highly exhausted chamber in the shape of an inverted U, which has a main light giving portion of uniform diameter and is expanded at each end into enlargements which are partly filled with mercury constituting electrodes. A condensing chamber is centrally located along the tubular portion to regulate the vapor pressure within the container.

Legal Notes

Public Use Proceedings.—Public use proceedings are initiated upon the petition of some person or persons believing they are in possession of evidence showing that the invention forming a part of the subject-matter or the entire subject-matter of an application for patent filed by another, was in public use or on sale more than two years prior to the filing of the application for patent. This question of public use is the only material one involved and in a recent case of *ex parte* Wenzelmann and Overholt, Mr. Billings, the first assistant commissioner, has held that a public use proceeding is not instituted to determine when the party filing the petition made the invention or whether he ever made it and that the sole question to be determined is whether the invention was in public use more than two years before the applicant filed his application

A Copyright Treaty Between the United States and Hungary.—The pirating of a play from the Hungarian and produced with much success in this country is said to be at the bottom of a copyright treaty recently concluded between the United States and Hungary. The treaty gives Americans the right to secure literary, artistic, dramatic, musical and photographic copyrights in Hungary on the same terms accorded to native Hungarians. In return, full copyright privileges are extended by the United States.

INQUIRY COLUMN

READ THIS COLUMN CAREFULLY You will find inquiries for certain classes of articles numbered in consecutive order If you manufacture these goods write us at once and we will send you the name and address of the party desiring the information There is no charge for this service *In every case it is necessary to give the number of the inquiry* Where manufacturers do not respond promptly the inquiry *may* be repeated.

MUNN & CO, INC

Inquiry No 9262 Wanted to buy a glass which is a conductor of electricity, and the address of the makers of the same

Inquiry No 9263 Wanted name and address of manufacturer of pantaloon stretchers with clamps which is capable of being folded up

Inquiry No 9264 Wanted the name and address of manufacturers of date pitting machines

Inquiry No 9265 Wanted the names and addresses of manufacturers of machinery for making picket fences

Inquiry No 9266 Wanted to buy machinery for fastening wire cloth to wooden frames with coppered tacks

Inquiry No 9267 Wanted addresses of manufacturers of metal specialties in connection with plate or window glass

Inquiry No 9272 Wanted names and addresses of engravers and mounters of fine quality maps or plans of large cities Large order

Inquiry No 9273 Wanted to buy a globe for a parlor fountain, working on the Heron system

Inquiry No 9274 Wanted the name of a manufacturer of a machine to make cushion covers for fruit crates

Inquiry No 9275 Wanted name and address of manufacturer of stock patterns of platen job printing presses

Inquiry No 9276 Wanted a household convenience and necessity which can be retailed at a profit at a price of from $1 00 to $2 00

Inquiry No 9277. Wanted a machine for packing dry batteries

Inquiry No 9278 Wanted a machine for separating crab meat from the shell

Inquiry No 9279 Wanted a machine for shredding asbestos board

Inquiry No 9280 Wanted names and addresses of manufacturers of machinery for stuffing dolls and teddy bears.

Inquiry No 9281 Wanted to buy machinery for bleaching walnuts and ivory nuts

Inquiry No 9282 Wanted name and address of manufacturer of coin-controlled gasoline-dispensing tanks for automobile use.

Inquiry No 9283. Wanted name and address of dealers in powdered Cocoa and Kola nuts in bulk.

Some Plastic Agglutinants

THE word "plastic" expresses the quality of bending, yielding, or flowing under pressure. Plasticity is a condition of fluidity, although it may be something more. Many metals are plastic; the flow of glaciers is due to the plasticity or fluidity of the component ice; the earth itself, in fact, flows or moves under pressure. Fibrous substances are not plastic, that is, they do not flow under pressure. Plasticity may be of a permanent character as in the case of asphalts and bitumens, lead and ice, or it may be only temporary as is the case with bodies having setting qualities, as plaster of Paris, caoutchouc and sulphur, phenol and formaldehyde, or clay before and after burning. In many instances the plastic agent is used with a filler of some inert material. That is, our plastic body is not only made to take some desired shape but it has to carry particles of some other material with it. Thus, a concrete block is a mass of gravel and sand held together by the cement; a piece of linoleum is a mass of cork dust held together by a set binder of linseed oil and sulphur or oxygen. The plastic substance must then have also agglutinating qualities, i e., it must adhere to the particles of whatever materials may be put with it.

This opens up a large subject. If the filler is of dense material like sand, say, the binder will hold such particles by mere surface adhesion. If the filler be porous, the particles become saturated with the binder and may be said to be anchored thereby, like particles of cork in linoleum or cellulose fiber in heavily sized paper In the first instance, the binder merely fills the voids between the particles of filler. In the second, the filler floats, as it were, in a saturating menstruum. If the first is of a kind that shrinks on setting or drying, it can not pull the particles completely together, and must either put itself under molecular strain or it must leave voids or openings in its mass. In the second instance, if the agglutinant is one that shrinks, the whole mass is merely pulled closer together or reduced in size; that is, the object shrinks on drying or setting.

Binders With Hydraulic Qualities.

Agglutinants or binders are of many kinds and uses Of one familiar type are those which have setting or hydraulic qualities. The most prominent exponent of this type is Portland cement Like all cements it has the property of setting, i e., absorbing water, and by means of this becoming hard and coherent The water in this instance becomes a part of the mass and helps to form a hydrated silicate or perhaps several, the exact nature of which is still somewhat in dispute.

Another common binder is plaster of Paris. This also possesses the property of hydrating Its uses in the arts are numerous, the most common being as an ingredient of wall-plaster, where it is combined with various agents for controlling or retarding the rapidity of its setting Mixed with alum it forms the material known as Keen's cement, from its discoverer—the alum making the plaster harder

Another binder is magnesium oxychloride When magnesia is mixed with a solution of magnesium chloride it forms a compound, an oxychloride, which is quite hard and wears well. It is a principal ingredient in many compositions for composite floors—in bathrooms, kitchens and similar locations. It has been proposed as a binder for fuel briquets

Linseed Oil and Vegetable Binders.

The number of binders of vegetable origin is legion. Probably the one most used is linseed oil If this oil be given a sufficient supply of oxygen it oxidizes into a resinous body—dries, as painters say. This drying can be accelerated by supplying it with an oxygen-transferring body—a catalyzer, lead oxide is the one generally used. The molecules of this will give off oxygen to the oil and in turn will take others from the surrounding air. Linseed oil is the main binder in linoleum, which consists mainly of ground cork held together by oxidized oil. Various mineral or vegetable fillers are added and, of course, coloring matter. Other oils have the same quality, one, Chinese oil, derived from the nut of the tung tree, in a degree even greater than that of linseed oil. This phenomenon of hardening is also in part the result of a polymerization—perhaps in several stages; that is, the molecules, at first of comparatively simple structure, unite to form molecules of more complex structure.

Gluten, gum arabic, dextrine, are also occasionally used, though their use is mainly that of simple adhesives. They are too brittle and too easily solvent to be very efficient as agglutinants. Starch is another often used. When boiled with alkali it acquires better adhesive qualities. These have no hardening qualities

Animal Agglutinants.

Glue or gelatine, casein and albumen are the animal agglutinants. These can all be hardened, i. e., rendered insoluble by treatment with various agents. Tannic acid is the oldest and best known for glue. It converts the soluble glue of the hide into an insoluble tannate which can only be broken up by prolonged treatment with alkali. Formaldehyde is another. Chromic acid, or compounds containing it, is another. These adhesives generally form the vehicles of the various sizes for paper, cloth, yarn and kalsomine. It may be stated here that the binders we have been discussing are nearly all to be found used as vehicles for pigments. A paint is more nearly liquid than the so-called plastic compositions hitherto discussed, but it consists essentially of a body of coloring matter—pigment, suspended in and held in place by a suitable menstruum. The menstruum becomes hard through the evaporation of a solvent, and through the resinification of the vehicle. Plastic and coating compositions are essentially the same and are in fact often interchangeable.

Cellulose Fiber in the Arts.

The most universal product of vegetation is cellulose fiber. If we separate fiber from the gums, resins and pectoses with which it is arranged in the structure of the plant we get, of course, pure cellulose, and if this mass of fiber be beaten, matted or felted together into a sheet or layer we get approximately pure paper, like filter paper or blotting paper. Cellulose fiber is insoluble in water, but if the fibers be pressed, crushed, rubbed together in water for a long time, hydration of the cellulose can be carried to such a degree that the filler breaks down and becomes a slimy mass which will dry bone hard. If a sheet of paper be heated in a concentrated solution of zinc chloride it is gradually dissolved. If this solution be squirted through a fine hole into alcohol a firm thread is produced which may be carbonized to make carbon lamp filaments. If the sheet of paper be incompletely gelatinized it becomes, after suitable treatment, vulcanized fiber. If a sheet be passed through sulphuric acid it becomes vegetable parchment. If a solution of cellulose be treated with carbon disulfid, a soluble syrupy compound is formed which separates into its constituents—alkali, carbon disulfid and cellulose. The amorphous cellulose thus obtained is known as viscose. It is used in sizing pulps and generally as a carrier or vehicle for coating paper and fabrics. It is also combined with cork, leather, etc., to form plastic masses. It may also be drawn into fine threads or filaments They are somewhat used as substitutes for silk but are weaker when wet than other artificially made filaments. They are not especially inflammable.

If a mass of pure fibrous cellulose be treated with a mixture of nitric and sulphuric acids there results a nitration of the cellulose and formation of nitrocellulose. The nitration may be carried to a varying extent, the N_2O_5 (nitric oxide) radical replacing the H in the cellulose, the mass formula of which is given as $C_{24}H_{40}O_{20}$, to any number, from one to twelve. Since N_2O_4 represents a strong oxidizing radical the higher nitrates are very rich in oxygen. They are therefore useful as explosives, gun cotton and smokeless powder containing them. The lower nitrates, while inflammable, are not readily explosive. When dissolved in suitable solvents, such as acetone and amyl acetate, they become the bases of pyroxyline compounds. Celluloid is nitro-cellulose mixed with camphor. It is not affected by moisture and it may be transparent if a proper solvent is used. It is useful as a varnish, though the objection to it here is that it does not stick readily to wood. It is used in the manufacture of buttons, combs and ornaments of various kinds, in making which it is generally mixed with a heavy charge of filler.

A solution of nitro-cellulose may be spun or squirted in the form of a fine filament from a suitable orifice into some medium which will dissolve or withdraw the solvent. This produces so-called artificial silk. A similar process is employed for making artificial horsehair and whalebone.

The Celluloid Industries.

Celluloid when deposited from many solvents is transparent. In thin sheets it is as transparent as glass without the slight greenish tinge which most glass, in the opinion of experts, imparts to objects seen through it. The fact that it can be made in bands of indefinite length renders it especially useful for picture films. These films are usually made by allowing a proper solution in a volatile solvent to fall upon a moving band or wheel. As the solvent evaporates, the film acquires coherence enough to let it be lifted off, dried and trimmed. It may be coated then or later with the proper sensitive emulsion. There are said to be three hundred moving picture theaters in New York alone, there are two hundred in Berlin, as many in Paris, and more in London. The demand for this purpose is said daily to amount to almost 600,000 meters—in value over a hundred thousand dollars. These films are inflammable to a high degree however. This has led inventors to attempt to find suitable substitutes. The best of these is probably cellulose acetate—a compound corresponding to cellulose nitrate with a corresponding change of acid. This changed result is attained usually by acetating hydrated cellulose and dissolving the product and treating as with nitro-cellulose. The cost is almost ten per cent higher but the product is not dangerously inflammable. It will, of course, burn like all organic substances, but it is no more inflammable than so much wood.

Chemists in certain German laboratories have been engaged for years in the analysis and synthesis of caoutchouc with a view to its commercial production. If vapors of turpentine be passed through a heated tube and condensed by a spray of hydrochloric acid, or the vapors be condensed and agitated with hydrochloric acid, solid caoutchouc (polyprene) will be formed. Another method recently discussed in this journal starts with starch, which, by fermentation, is partly converted into fusel oil, i. e., the higher alcohols These, by subsequent treatment, are converted into isoprene, which changes readily into polyprene. This seems easy, and there are other processes which seem just as easy, but natural rubber either from plantation or from forests is still the main source of supply. A limited supply is obtained in the southern part of the United States, and from Mexico, from a desert shrub called the Guayule. All natural rubbers contain a varying percentage of resins and gums other than rubber—and Guayule is no exception. The purest in this respect is that known from its principal place of export as Para rubber. There are more than one hundred and fifty plants from which rubber of one grade or another is derived.

Crude rubber is of little use as such. It is too soft and runny. It is usually compounded with sulphur, which hardens and fixes it. The product, according to the proportion of sulphur used, is known as soft or hard rubber. Rubber is ordinarily adulterated with a large per cent of substitutes and is charged with a variety of fillers.

There are so-called rubber articles made which do not have one per cent of pure new rubber. They have rubber substitutes—oils, particularly corn-oil, and reclaimed rubber, with various other cheaper mineral or vegetable diluents.

It is used rather for its elastic, insulating and waterproofing qualities. It is not preeminent as agglutinant merely.

Bituminous and asphaltic binders are mostly used in binding aggregates for

street use. The ordinary asphalt street pavement consists of a layer or blanket of asphalt and some fine filler, resting upon a foundation, generally of bituminous or hydraulic concrete or both. The asphalt has no particular strength of its own. It is the roof for the structure below. It must stretch during shrinking by cold, it must shed water, it must not crack, it must not flow when the summer sun beats upon it, and it must give a sufficiently gritty hold to hoof and tire. Asphalt seems well adapted for these purposes. Asphalt is also the basis of many paints, varnishes and japans.

Substitutes for Celluloid.

If a mixture of carbolic acid and formaldehyde be heated an oily viscous liquid soluble in alcohol and acetone will be produced. If this be heated under pressure at a temperature above the boiling point of water, a hard, brittle, insoluble, infusible and otherwise refractory substance will be produced. If the treatment is stopped before reaction is complete, the result of the reaction may be powdered and placed in molds and again heated. This is the substance known as bakelite. Other similar products are on the market. This product lacks the elasticity of celluloid, but it is harder and is incombustible as well as infusible. It may be combined with fillers of various kinds, and for many purposes is obviously better than celluloid.

In cork-soled shoes the bottom of the shoe is filled in with a mixture of ground cork and gutta percha or similar gum and a suitable solvent. This is d fficult to work, is expensive, and the solvent makes it inflammable. Wax tailings, a residuum of petroleum distillation modified by various agents, has been successfully used instead. It is said to obviate many of the objections to which the gutta percha or similar binding agent is liable.

The foregoing indicates to some extent some of the most used plastic agglutimants. It would be easy to extend the list. The fillers being for the most part neutral, no discussion of them has been attempted. The same binder may be used for making artificial stone for carrying a wall pigment, for laying the dust on a highway, or for making a fuel briquet.

Recent Research on Lubrication for Gasoline Engines

By Theo. M. R. von Keler

THE lubrication of gasoline engines presents a problem materially different from that which confronts us in ordinary steam engine practice. This is immediately evident when we consider that the temperature in the cylinder of a steam engine may at most reach about 500 deg. Fahr., while in an internal combustion engine it rises as high as 2,640 deg. Fahr. Added to this is the fact that the piston speed in a gasoline engine is considerably greater than in a steam engine. Just what happens to the lubricating oil in the operation of a gasoline engine is not precisely known, but there can be no question that a considerable portion of it burns and is discharged in the exhaust. How much of the oil is destroyed, and how much remains to do its duty as a lubricator, depends on the composition of the lubricant, and the cooling arrangement of the motor.

There is no doubt that the destruction of the oil by combustion cannot be averted; a certain quantity of the oil *must* burn, and *must* find its way in this burned state into the exhaust pipe. If this combustion can be made complete, in so far as the burnt part of the oil is concerned, it follows that there will be less residue and less "smoke." A very thick oil, composed of fractions with a high boiling point, naturally will be only partially burned, which would explain the almost universal demand that cylinder oil be medium thick and possess a comparatively low boiling point—just the opposite from what the average driver or owner of a car would imagine would be necessary. The part of the oil which burns, must burn completely and should not leave a carbon deposit in the cylinders. The more carbon there is in the oil, the more oxygen is necessary to complete combustion. Oxygen, however, in a gasoline motor is a precious substance and practically the entire supply drawn into the cylinder on the suction stroke is needed for the combustion of the gasoline itself. The small quantity not thus employed is sufficient for complete combustion of the oil only when the latter does not contain too much carbon.

A series of tests has just been completed at the Royal Experiment Station for Testing Materials at Berlin, Germany, which disclosed some unexpected and highly valuable properties of oil of different chemical composition. The oils examined were separated into two portions by extraction with acetone, which dissolves the heavier constituents of the oil. It was found that "treated" oils, that is to say those from which the heavier portion had been extracted with acetone, gave an exhaust free from irritating odor, while the untreated oil, under similar circumstances, gave rise to pungent smoke, highly irritating to the nose and eyes. It is thus conclusively shown that the offensive products in the exhaust are due to the heavier constituents of the oil.

These tests show also that the various means taken or proposed which are to do away with the nuisance of smoking automobiles do not attack the problem from the correct point. It is not so much a question of absorbing or deodorizing the exhaust gases, as of a proper selection of the oil best suited for the particular motor in which it is to be used. And this selection should not be made by some sort of "rule of thumb" method, but by a careful analysis based on the acetone method. Once decided upon as the best, the oil selected can undoubtedly be obtained from the manufacturers. It would even be possible to divide the oils into specially light ones for automobile use, and heavy ones for steam engines—or to treat them with acetone before marketing them.

Aside from the treatment of lubricating oils with acetone, the science of chemistry knows of no method of analysis at present, which permits of a correct valuation of lubricating oil for combustion motors. Research is going on in practically every large laboratory, and especially in the great automobile factories and oil refineries, but so far no satisfactory method has been found, by which the quality of an oil for automobile use can be ascertained in the laboratory. It is, however, expected that further tests along the line of acetone treatment will evolve a fairly easy, and yet trusty, method of judging the suitability of the various kinds of lubricating oil for automobile use.

[The foregoing is an abstract of a paper of a more technical character, which is published at length in the current number of the SCIENTIFIC AMERICAN SUPPLEMENT.—EDITOR.]

Temperance Beer

IN prohibition States or localities a non-alcoholic malt beverage has been put on the market. This so-called temperance beer must contain less than ½ per cent of alcohol by volume, or it will be subject to the United States internal revenue tax. (See Treasury Decision, No. 1,360, May 19th, 1908.) The aim has been to manufacture a temperance beer containing all the ingredients of normal beer except the alcohol, and which shall resemble it in color, flavor and taste as nearly as possible. There are several methods of making temperance beer. Alcohol is removed from normal beer by methods of careful distillation at low temperature. Hot air or carbonic acid gas is blown through the beer to distill off the alcohol. In this connection the sensitiveness of the albuminoids above referred to should be remembered. After cooling, the non-alcoholic beer is recarbonated with carbonic acid gas. Another method is [illegible]

manufacture in such a manner as to keep the alcohol below ½ per cent. This may be done by stopping the fermentation, sterilizing and recarbonating. Still another method is by mixing normal beer, beer wort and water in proper proportion and carbonating. It is difficult to make a temperance beer that will taste like normal beer, and its keeping qualities are poor. Moreover, the manufacture of good temperance beer is more expensive than that of normal beer, because of the additional manipulations required. It has occurred, therefore, that retailers have sold normal beer for temperance beer and got themselves into trouble by doing so. Probably this is the only instance where a dealer was legally prosecuted for selling the genuine article for the alleged substitute, and this in face of the fact that the consumers made no complaints, but were perfectly satisfied.

The Road Congress

SCIENTIFIC management as applied to the nation-wide problem of building and supervising public roads is to be the keynote of the American Road Congress, to be held on the Million Dollar Pier in Atlantic City, September 30th to October 5th.

The movement for better roads has taken root in every State in the Union. In every community there are men laboring for better roads. The trouble with the movement has been its lack of definite plans and methods for handling the immense problem. The plans and methods are provided at the Atlantic City Congress.

It is not merely to create enthusiasm for an improved system of public roads that the congress is to be held. The enthusiasm is already at hand. The purpose of the congress, which marks the consolidation of the convention interests of the American Association for Highway Improvement, the American Automobile Association and the National Association of Machinery and Material Manufacturers, is to deal with every phase of the road subject in an orderly and scientific manner.

The people of the United States are now spending, for instance, more than $150,000,000 a year on their roads. It is known that they are not getting a full dollar's worth of good road for every dollar expended. In other words, many millions of dollars expended for roads are actually wasted every year because of unscientific methods. Some communities do not build the right kind of roads. Some build roads designed for light traffic and expect them to withstand heavy traffic, and some build expensive roads where inexpensive ones would give better satisfaction. Much of the trouble is due to the fact that there is an absence of scientific supervision of construction and maintenance. There are more than 100,000 officials of more or less importance engaged in the work of supervising the roads of the country, and many of these officials are engaged for political reasons, and not for their ability or competence.

At the American Road Congress civil service will be thoroughly considered in its application to road management. Gen. John C. Black, chairman of the United States Civil Service Commission, will make one of the addresses on this subject. He will explain the importance of putting the civil service, or merit test, to every man having anything to do with the supervision of the roads.

Every other phase of the road subject will be handled in the same scientific manner. The most eminent bankers will discuss methods for safeguarding a proper accounting of taxes and assuring business methods in obtaining loans or making bond issues to build good roads. There is to be a legislative section which will endeavor to point the way to needed reforms in road legislation. The president of the American Bar Association is lending his assistance in preparing the programme for this particular section of the congress.

In conjunction with the congress, there will be a conference of educators with a view to having highway engineering introduced in colleges on a scale that will meet modern requirements. Engineers experienced in road building are not plentiful, and if the colleges could be induced to introduce the right kind of courses, one of the greatest needs of the road movement would be supplied.

It is believed by President Taft, who is the honorary president of the American Road Congress, that better roads mean greater happiness not merely to persons living in the country districts, but to every human being in the country. Better roads mean that the farmer can haul his products at all seasons of the year, doing away with the railroad waste of pulling empty cars back and forth at certain seasons of the year, lowering the general cost of transportation, and finally resulting in a cut in the cost of living to the consumer. President Taft, who is to make an address at the opening of the congress, will point out that the improvement of public roads is the best investment that the American people can make. Of equal interest will be the address to be made by Governor Wilson of New Jersey.

The American Road Congress will be notable in that it will mark the evolution of the road movement from the theoretical to the practical stage. Each phase of the big subject will be handled by the foremost men in that particular line of endeavor. It is felt that scientific management is as applicable to a great subject of this kind as it is to the business of a great corporation. Logan Waller Page, director of the Office of Public Roads, and active president of the congress, believes that the gathering in Atlantic City will put the road movement on such a basis that the time will not be long distant when twenty per cent of the public highways will have been improved. Mr. Page estimates that the improvement of twenty per cent of the roads will bring this nation's road system to a high point of efficiency, almost equal to that of France.

A Substitute for Wood

THE steadily increasing price of timber in Europe has caused interest to be centered in a French invention for preparing a substitute for this article. The process is very simple and inexpensive, the whole process of manufacture being carried out by a single machine. The inventor, Monsieur Carré, associated with the champagne industry, embarked upon this task with a view to preparing an efficient and cheap substitute for packing the bottles of wine, as well as the cases which at present are made of wood, and the cost of which is persistently rising. The first experiments were made about five years ago, and recently some excellent specimens of the substitute have been produced.

The material used in this process is straw. The straw is first split lengthwise [illegible] the resiliency in the stalk. The ripped material is then placed in the machine together with certain ingredients, being laid upon a traveling plate. The latter is kept at a certain uniform temperature by means of steam, so as to cook the straw and the substances associated therewith. When this stage has been carried to the requisite degree intense pressure is applied the results of which are to knit or compress the fibers of straw very closely and tightly together, to form a homogeneous mass. A pressure of between two and three tons per square inch is required in order to produce the best results, and the fabric issues from the machine in continuous lengths of the required thickness and width to be sawn as desired.

In general appearance the material resembles whitewood, the compressed straw

imparting a straight grain-like effect. It works fairly easily, and when sawn leaves a clean cut. Its strength is comparable with the ordinary whitewood, and it can be applied to all purposes for which the latter is fitted. In the preparation of the greater thicknesses such as for joists or posts the better practice is to build up the baulk with layers about a quarter of an inch in thickness laid transversely. Tests with the material have shown that when the cooking and pressing operations have been carried out accurately, the fabric will not disintegrate, and responds readily to the application of tools, though being somewhat denser than whitewood it is harder to work across the grain. It does not split readily when nailed, and should, therefore, prove highly serviceable for making packing cases.

One highly useful application of the invention has been found. This is the production of cordwood for burning purposes. Efforts are being made to introduce it into the Canadian West on the wheatfields of which the straw at present is a waste product, while wood and other fuel is expensive. By means of this machine rough wood suited to burning purposes could be prepared very cheaply. The artificial wood burns with a bright long flame, is practically free from smoke, and gives intense heat, so that it is well suited to steam raising purposes.

The inventor has also devised a means of manufacturing matches from this substitute. This was not an easy matter as the ingredients associated with the raw straw had to be of such a character that they emitted no smell, smoke, and yet burned with a steady flame, as well as igniting readily. Success has been achieved in this connection and an ingenious machine has been devised. In this case the molding plates, both upper and lower, have been corrugated to form round grooves about a millimeter less in diameter than the square section Swedish matches. The plate is made in segments, each of which corresponds to the length of the match, these segments being hinged together so as to travel round the cylinder in the compressing machine, and are ejected in long rows ready for receiving the heads. If desired, however, the matches can be produced in blocks joined together at the lower end similar to the wooden matches that are found in the West, and being torn singly from the block as required.

The matches produced in this manner are similar to the ordinary wooden type, burn readily, while the head and consumed part do not drop off. The cost of manufacturing by this method is less than that of fashioning them from wood, though they are equal to the latter article in every other respect. In the latest experiments the inventor has succeeded in producing an excellent substitute for the wax match, dispensing with the cotton fiber foundation of the latter article.

Another application of the same idea has been the manufacture of a corrugated packing material to take the place of the corrugated strawboard which is used so extensively for wrapping purposes. This product is far stronger than the strawboard article, possesses equal resiliency, and rolls closer when required, so that it constitutes an excellent medium for bottle packing. It is neater and cleaner than the straw packing generally employed for wrapping wines, and after fulfilling this purpose can be subjected to other packing uses.

A Simple and Efficient Canoe Gum

CONSIDERABLE need is often experienced by canoeists and boatmen generally in the lack of a good canoe gum to stop leaks or breaks which may occur in the calking of the boat. When canoeing in the northern waters of Canada or on the lakes in the Adirondacks and the Rockies, it is often inconvenient or impossible to obtain a ready-made gum which will answer this purpose.

A good canoe gum must answer several demands; first, it must be sufficiently pliable so as not to break and powder when in the cold water and under strain, second, it must not melt and run in the sun when the canoe is beached for a short time; third, it must not dissolve or soften when in the water; and last, it must set hard in a few moments if it is to meet the requirements of an emergency. It goes without saying that the raw material must be easily accessible, and the price as low as possible.

All these demands are adequately met by a gum compounded of rosin and vaseline, and the gum can be made in any watertight dish which may be heated over an open fire. One part of vaseline and four parts of rosin, by weight, heated until dissolved in each other will give a gum which, at summer temperature, is soft and easily dented. This is the consistency required for a gum to prevent crumbling in cold waters, such as Lake Superior.

A material compounded of 10 per cent vaseline and 90 per cent rosin is quite brittle when cold. However, in warmer waters farther south, this gum is sufficiently pliable and does not soften or melt readily in the sun.

Addition of rosin makes the gum harder and more brittle, adding more vaseline makes it softer and tougher, so that any consistency may be had from the hardness of rosin to the softness of vaseline.

The above ingredients compounded in the proportions of 10 to 20 per cent of vaseline and 90 to 80 per cent of rosin will answer all the requirements of a first-class canoe gum. It may be carried in a tin or wrapped in paper, and it melts easily over the flame of a match and sticks like glue to warmed surfaces. Any coloring matter may be stirred into the hot liquid gum; for example, Chinese blue gives a bluish green color, red lead gives a brilliant red, and chrome green yields a brilliant green. The best proportions are one part of mineral pigment to one part of gum. The addition of pigments makes the gum very hard.

The Current Supplement

THIS week's copy of the SUPPLEMENT forms a companion issue to the present Chemistry Number of the SCIENTIFIC AMERICAN. Mr. August Neumark, who, by this time, must be known to our readers from several very good articles which he has contributed, gives us the first installment of an article on Nitrous Oxide and its Applications, which will run through two issues.—An article by Dr. Raschig on Soluble Gunpowder touches on an important new development.—Mr. C. C. Hutchins describes the laboratory preparation of quartz fibers.—Welding by electricity is becoming more and more important. Our front page illustration forms part of an article on the subject.—Prof. Gockel writes on the Correlation Between Sun Spots and the Weather.—Mr. Carroll Curtis contributes an excellent article on the *East Coast Fishing Banks and the Preservation of Our Fish Supply*.—One of the most important articles in this issue is from the pen of Mr. von Keler on Lubrication Problems in Gasoline Engines.—Another important subject dealt with is the Manufacture of Ethyl Alcohol from Wood Waste.—Prof. Bone recently delivered a lecture before the Chemical Society at Leeds on his "Surface Combustion Furnaces," which seem to be destined to work a revolution in industrial heating operations. An illustrated abstract of this lecture is published in this issue.—Mr. Johnson describes an ingenious machine for testing iron and steel for their magnetic properties and recording the results graphically.—Using X rays to fit shoes on one's feet may seem at first sight a trivial application, but when it comes to supplying an army with foot-gear, the matter assumes grave importance. An illustrated article tells of a new departure in this direction.

RECENTLY PATENTED INVENTIONS.

These columns are open to all patentees. The notices are inserted by special arrangement with the inventors. Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN.

Pertaining to Apparel.

INNERSOLE.—F. L. COASON, 87 Winter St., Rochester, N. H. The innersole is constructed of unusually thin leather, and is reinforced by a ribbed canvas member sewed to the innersole at each side of the rib, so that when the welt and upper are sewed to the canvas member rib the innersole will be reinforced by the canvas and the strain will be distributed on the innersole at each side of the rib.

Pertaining to Aviation.

AERIAL PROPELLER.—HARRY H. ELLIOTT, Lawrence, Kan. The principal feature here is the propeller's variable pitch alterable at will by operating the lever, wheel or other suitable device, and the blades can be set or adjusted so as to give a thrust or pull or neither, when they are rotated. If the propeller is used on a monoplane and mounted in front to give a pull, its reverse position or thrust will act as a brake in case a sudden stop is necessary or desired. For starting or for excess speed or wherever a maximum thrust is desired, it is instantly obtainable and can be maintained. The neutral position is equivalent to a free engine and makes the aviator independent of personal aid when starting. Construction is exceedingly simple, and only a few minutes are required to "take down" the propeller for packing, which can be done in half the space needed for the ordinary wooden propeller. All parts are interchangeable, and an accident to one part, a blade, for example, can be replaced without obtaining a whole new propeller.

MULTIPLEX POWER FLYING MACHINE.—C. V. JOHNSON, Box 1896, Goldfield, Nev. An object here is to obviate the necessity of any great skill of the aviator in case a motive means should give out, by providing a plurality of motors adapted to drive one or more propellers, so that if one is disabled, the other or others will automatically take up the work, keeping up the aeroplane's speed and thus removing any chance of disastrous results on this account.

Electrical Devices.

OVERHEAD TROLLEY.—R. A. PROLAR, 286 Pope Ave., Toronto, Canada. In this case the trolley rope is wound on a spring-retracted drum which is automatically released when the trolley wheel is displaced from the wire, and whereby the rope is taken up, or wound on the drum, and thus the trolley wheel is drawn down below the wire into position to be easily and quickly reapplied thereto.

ELECTROMAGNETIC DEVICE.—B. SOLDATENKOW, 87 Rue La Pérouse, Paris, France. This invention relates to an electro-magnetic device having a variable action, and it is intended to enable different and distinct effects to be obtained by the action of a single solenoid and a single electric circuit. It can be applied to actuation of apparatus of all kinds, or to the production of electrical, electro-magnetic, or mechanical effects.

PRINTING TELEGRAPH.—B. SOLDATENKOW, 87 Rue La Pérouse, Paris, France. This invention comprises an electro-magnetic device having two distinct actions and provided with a single solenoid by which means it is possible to obtain different and distinct effects. It is thereby possible to reduce the consumption of current, as well as size and cost of apparatus.

ELECTROPLATING APPARATUS.—J. W. DOW, 564 Park Ave., W., Mansfield, Ohio. Mr. Dow's invention relates generally to electroplating apparatus and more particularly it is directed to a new and improved construction adapted for use in depositing metals upon bodies, the construction being especially adapted for use in electroplating small bodies.

Of Interest to Farmers.

SELF PITCHER.—O. D. HUTTO, Russell Springs, Kan. This invention relates to an agricultural machine for taking or gathering grain from stacks and conveying it to a threshing machine or the like. The object of the inventor is to provide a simple machine requiring but little attention for adjustment and operation.

Of General Interest.

DEVICE FOR DEVELOPING PHOTOGRAPHIC FILMS.—DR. W. R. INGRAM, 735 So. 6th Ave., Tucson, Ariz. An object of the invention is to provide a device having a retainer for each film, the retainers being hinged together and so formed that they may be rolled up in compact form, thereby occupying little space and necessitating a minimum quantity of developer.

PIANO SOUNDING BOARD.—F. B. LONG, 724 So. Broadway, Los Angeles, Cal. The invention provides a sounding board for pianos and similar stringed musical instruments arranged to permit of maintaining the original crown and the desired firmness of the structure to insure the production of a well-sustained tone when the piano is played.

CLOTHES LINE SUPPORT.—E. [illegible], [illegible] Ave., New York, N. Y. This invention provides a support on which laundry may be hung out to dry from the window, the parts being managed from within the room; provides means for forming a passageway through the support; provides within the room from which the windows opens to move the laundry to the outer end of the rack; and provides means for forming a central passage through the rack.

ALUMINIUM SOLDER.—C. R. EAKENS, 416 Van Der Venter Ave., Astoria, Long Island City, N. Y. This invention relates to an alloy to be used as a solder for uniting one strip or piece of aluminium to another, or for uniting one piece of aluminium to any other suitable metal. The solder may be used for the purpose stated without the heating of the parts to be united by a blow pipe or otherwise.

DESK.—S. GARAVAGNO, care of D. Garcia, Lagos, Box 5, Montevideo, Uruguay, South America. This desk is of compact form with flexible roll-top and a tilting shelf and occupies a minimum of space and has extensible members to give the requisite area when in operation; is provided with an attachment for latching an extended leaf in operative position; and is provided with means for holding the shelf in advanced or retracted position. It is for use with typewriting machines, stands for automatic music machines, sewing machines, etc.

ADJUSTABLE SCHOOL DESK AND SEAT.—S. MACC. JONES, Box 76, 1425 Superior St., Wilkinsburg, Pa. This invention relates to desks and seats for audience rooms, especially school rooms where it is desirable for the furniture to be adjusted in accordance with the stature of the several persons to use the same. The inventor has found by practical experience that the number of different sizes of school desks made in accordance with his invention may be reduced even more than one half, and yet easily come within the requirements of the law in some jurisdictions.

HEAT INSULATED RECEPTACLE.—R. HARTWIG, 12 Bregenzerstrasse, Berlin, Germany. Mr. Hartwig's invention consists essentially in providing within a vessel a joint adapted to be sealed, and providing this joint with a tensioning device, comprising the insulating ring, near the upper edge of the receptacle, and the inventor prefers to arrange the tensioning device between the inner and outer bottoms of the receptacle.

PROPELLER.—D. H. BLAKE, care of J. W. Happle, Sanderson, Texas. This invention relates to marine propellers, and the aim is to provide a form designed to give increased efficiency in proportion to its size, and to provide in connection with the improved propeller novel means of preventing a vacuum behind the propeller.

VAULT COVER.—H. SELLHEIM, 357 Stockholm St., Ridgewood, Brooklyn, N. Y. This cover is for use for cellars, vaults and the like, and is adapted to form a strong surface which will at the same time permit the passage of light to the cellar or vault below. In this device the transparent members or lenses can be readily removed, for the purpose of renewing the same.

Hardware and Tools.

WIRE ANCHOR.—F. T. REINERT, R. F. D. No. 3, Box 1, Aurora, Ill. This improvement relates to devices for connecting or anchoring the ends of fence wire or the like to posts. The anchor is preferably made of metal which may be of any suitable variety having in view the elements of cheapness and strength, and it may be galvanized for durability and appearance.

TOOL HANDLE HOLDER.—C. BERRY, care of Central Hotel, Grand Forks, N. D. This invention pertains especially to devices whereby a single holder may be used successively for attaching a single handle to various tools of similar or different character, or for the renewal of a broken or defective handle on a certain tool or set of tools such as garden rakes, hoes, forks, chisels, screw drivers and the like.

Machines and Mechanical Devices.

OIL SWAB HOLDER.—C. E. CALKINS, Las Cascadas, Canal Zone, Panama. The holder is the form of a cup constructed in two half sections hinged together so that they may be closed about a piston rod. The covers of the holder have flanges that are caught under lugs on the cup sections. A single screw thus holds the cup together and also locks the cover sections.

CHUCK.—F. J. CORNIL, 223 Cypress St., Argenta, Ark. This invention is a combination chuck whereby thin cylindrical work can be held by pressure from both inside and outside at the same time, thereby eliminating distortion. The jaws, which are reversible can be used in the usual manner, and also for clamping work thereto, said work being centered by lugs, and the clamps forming part of the jaws. A locking device for the jaws is included.

SUCTION WATER MOTOR.—J. O. KAFADER, Fort Bidwell, Cal. The purpose in this case is to provide a motor wherein the difference in height between two strata of the earth is utilized to create a suction adapted to aid in the operation of a motor, which in turn pumps water from the upper stratum, which is partly utilized, and any excess therefrom stored for other use.

VITASCOPE.—F. J. MUKAUTZ, 1650 E. 55th St., Cleveland, Ohio. This apparatus is for use in connection with a phonograph, the ar-

rangement being such that both instruments move in unison, so that persons may be represented upon a screen in an act or in conversation, the words for the lines which the actors are supposed to say being supplied by the phonograph at the appropriate time.

MACHINE FOR TESTING MATERIALS.—H. Schiller, manager, 150 Engerthstrasse, Vienna, XX/2, Austria. The object of this inventor is to provide a press of such a shape and arrangement of its parts that not only annular or tubular work-pieces, but also rod-shaped trial-pieces can be tested, both as to tensile strength and also as to resistance to collapse or buckling resistance.

SCREENING DEVICE.—O. R. Smith, care of J. F. Carson, Box 141, Mullan, Idaho. This device relates to a new and improved screening mechanism used in the separation of different sized materials, and may be used at any place where it is desired to separate materials, as, for instance, grain, seed, ores, sand, different sized materials, etc.

Prime Movers and Their Accessories.

GASOLENE SPRAY OR VAPORIZER VALVE.—Quincy Engine Company, Quincy, Pa. The object of this improvement is to provide a device especially adapted to automatically regulate the fuel charge for explosion engines, both as regards the amount and relative proportion of ingredients of the mixture in accordance with the conditions to be met.

Railways and Their Accessories.

AUTOMATIC COUPLING DEVICE.—F. J. Fitch and G. Bausback, Center and Market Sts., Pottsville, Pa. An object here is to provide a device which will automatically connect the main train pipe section, the steam pipes for heating the cars, and air pipe for signalling purposes and electric circuits for lighting or signaling. A further object is to provide a coupling head having a removable head in which the gaskets are disposed, thereby facilitating removal and replacements of the gaskets.

Pertaining to Recreation.

PUZZLE TOY.—A. L. Pooler, 24 Hammond St., Bangor, Maine. This invention comprehends a movable figure causing amusement because of the fantastic position it assumes, and as a puzzle the device constitutes a means of exciting great curiosity in attempting to change the figure from one extreme position to another.

Pertaining to Vehicles.

VEHICLE WHEEL.—J. W. McCallum, Plymouth, Ind. This wheel is adapted to be assembled and bound together to form a continuous wheel from segments adapted to be assembled and bound together to form a continuous wheel; the segments are formed so that the members thereof are integrally related; and the maximum rigidity is obtained with a minimum weight.

LIGHTING SYSTEM FOR VEHICLES.—L. R. Duval, 558 Clinton Ave., Union Hill, N. J. This invention refers to electric lighting systems for use on motor vehicles, and more particularly to that type of system in which there is employed a dynamo driven from the engine for generating the necessary current for the side and tail lights and the search-lights.

Designs.

DESIGN FOR A SETTING FOR GEMS.—H. Ackerman, Weehawken, N. J. The shape of the base is circular, and the edge comprises six ornamental formations. The side elevation of the design is flaring and slants down toward the base.

DESIGN FOR A LAMP SHADE.—J. Fairburn, Manhattan, N. Y., N. Y. This ornamental design for a lamp shade has the characteristic of extreme simplicity of form which nevertheless secures a very graceful result, both in plan presentation and side elevation view.

Note.—Copies of any of these patents will be furnished by the Scientific American for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

We wish to call attention to the fact that we are in a position to render competent services in every branch of patent or trade-mark work. Our staff is composed of mechanical, electrical and chemical experts, thoroughly trained to prepare and prosecute all patent applications, irrespective of the complex nature of the subject matter involved, or of the specialized, technical, or scientific knowledge required therefor.

We are prepared to render opinions as to validity or infringement of patents, or with regard to conflicts arising in trade-mark and unfair competition matters.

We also have associates throughout the world, who assist in the prosecution of patent and trade-mark applications filed in all countries foreign to the United States.

Sulphur at Home and Abroad

(Concluded from page 139.)

tion of sulphur in all the United States had not reached as high as 5,000 standard tons per annum, but due to the opening up of the Louisiana deposit, the figure jumped to 127,000 tons in 1904, and 360,444 tons in 1908. Since that year it has fluctuated around 250,000 tons, and last year totaled 265,664 tons. The yearly production of the Japanese mines averages about 40,000 tons, which is marketed principally in Australia.

The American sulphur interests were, prior to the outbreak of the war with Turkey, credited by the Italians with having obtained control of the sulphur fields of Cyrenaica—fields that extend along the desolate shore of the Gulf of Sidra, which the Arabs call Giun-el-Kebrit, or the "gulf of sulphur," just as they call the immediate region of the sulphur deposits Gebel-el-Kebrit, or the "zone of sulphur."

The alarm of the Italians arose from the landing in Cyrenaica from the private yacht of Allison V. Armour, a little less than two years ago, of a scientific expedition sent thither by the Archeological Institute of America, and headed by Prof. Richard Norton, of Harvard University. The purpose of this expedition was to excavate the ruins of the ancient city of Cyrene, the site of which is more than two hundred miles eastward of the sulphur territory.

A rumor that the Turkish Government had granted a concession to Americans for the exploitation of the Cyrenaica deposits was so far credited in Sicily as to be made the subject of an interpellative protest in the Italian parliament in February, 1911, by Deputy Vaccaro, of the Sicilian province of Girgenti, where the world's oldest sulphur operations mainly center.

It was pointed out by the southern deputy that "such a concession would fatally compromise the Sicilian industry," which, he asserted, could absolutely not resist the competition of an American company exploiting the Cyrenaica field.

In the month following the deputy's query, news came from Cyrene that Herbert Fletcher de Cou, of Michigan, one of the members of the American archeological expedition, had been slain by a hired trio of Arab assassins. The official report of the murder, as made to the Archeological Institute of America by Prof. Norton, contained the significant statement that "the Italians had spread false reports about my intentions; . . . that our true purpose was not to dig the ruins, but to mine for sulphur."

It is a favorite theory of Italian geologists that the island of Sicily, instead of being a detached part of the continent of Europe, in a prehistoric age formed the northernmost part of Africa. Those who hold to this belief regard the rich and abundant sulphur deposits of Sicily as the logical conclusion of a virgin stratification that must have its origin in the low mountain range that forms the plateau of Aurigi, to southward of the coastal plain of Cyrenaica. On this coastal plain, in the region of Gebel-el-Kebrit, the evidences of sulphur wealth have revealed themselves to modern science, not as a compact and well-defined area, such as Sicily's, but as a straggling drift, emanating from what, farther inland, must prove to be an exceedingly bountiful store of the mineral. However, it is only that part of the coast territory of Cyrenaica lying within a few days' journey by horseback from the sea that has been explored by Europeans competent to judge of sulphur productivity.

An authority recently delegated by the Italian Government to investigate and report upon the sulphur prospects of Cyrenaica was Dr. Salvatore Giannò, who visited the country in the capacity of commercial *attaché* of the Italian legation at Constantinople. Writing in the *Rivista Coloniale*, organ of the Italian Colonial Institute, Dr. Giannò lately observed:

It appears evident that the sulphur zone in Cyrenaica describes an angle from Muktar, Oasis of Abu-Naim, Hara-Dedba, ...

ing a line of resistance to the rich mineral drift of the Sicilian coast, which, starting from the base of Mount Etna, follows the mountainous chain to Lecara, and thence to the mountains of Gibellina. . . . The sulphurous stratum, therefore, in Cyrenaica, lacking a scientific exploration in the true sense of the word, may not, indeed, must not, be restricted to the known deposits, or to those caves, or quarries, exploited crudely and in embryo by the Arabs, but must be found to follow the mountainous line that stretches from Ara dei *Fileni* to confine the Plain of Barca.

That low chain of mountains which extends from Sebka-Muktar to Gebel-el-Ala, to Gebel-dj-Djeria, to Frerin, to Maradek, to Marsa-Braiga, and so to Hara-Docha, is a vast deposit of sulphur, part explored, but the greater part unexplored. From ancient times the inhabitants of the region have been given to a superficial working of the deposits, not for the uses wherefor sulphur is most in demand by the market, but for that, infinitely more modest, of doctoring camels afflicted with the mange, and the outlet on the sea, or gulf, for the product, is always the port of Marsa Braiga, whence the sulphur is dispatched by sailing vessels to the caravan ports—Tripoli, Benghazi, Alexandria.

To the south of Marsa-Braiga, a small natural port on the Gulf of the Great Sidra, there is a quarry already in operation. It is called Kofra-el-Kebrit (Cave of Sulphur) and from this the Arabs extract the product. This quarry is distant about twelve hours from the shore. Another deposit, which I believe to be the richer, is found to the southwest of Gebel-dj-Djeria. This follows the little mountainous chain extending from Muktar to Hara-Docha, and the stratum is so ample that it is to be traced in four days' journey by horse in the direction of the meridian. The quality of this sulphur is of the best, and the mineral, without being attached to the rock, presents itself in a purer state, and in greater quantity as depth is attained.

The richness of the mineral, from examinations made on the field of the quarries in operation, needs not to be discussed; from experiments made it yields an *ottavo* of purity . . . The primitive and superficial operations of the Arabs in the aforesaid quarries indicate that the mineral they obtain is that which is found in the first stratum—exposed, as it were, at but a few meters of depth; while at the second stratum there is always observed a sure improvement in the quality of the mineral, and at the third stratum it betters in exact ratio to the depth attained. Where thick, the sulphur is found to be richer than where it is submerged in water.

Sugar Beet Industry of Germany

(Concluded from page 134.)

The thinning of the beets as well as their cultivation is a work to which (according to the German idea) women are especially adapted. Their wages as field hands are only about 60 per cent that of men, although in this kind of work they do about as much. The extension of sugar beet growing in Germany quickly brought about a shortage of labor and caused the introduction of what is known as the "season workers" or immigrant laborers, who are brought in to work during the beet season, and at the close of it are sent back to where they came from. Every spring hundreds of thousands, in recent years over 400,000 men and women, come from the eastern provinces of Germany, from Russia, Hungary and Bohemia, to the central and western provinces of Germany to work, principally in the sugar beet fields.

So important has this large movement of foreign laborers become that legislation has been passed specifying the time (15th of November for central Germany) by which they must all be returned.

The large property owners have made special provisions for caring for this foreign labor by erecting barracks for them to live in. In addition to a cash wage, an allowance is given in provisions such as potatoes, meat and flour. The beet growers prefer to get as large a proportion of women as they can, and as a consequence many more women than men are to be seen working in the German beet fields.

The influx of such large numbers of foreign workers onto the farms during the summer months naturally has a detrimental effect, both socially and morally, and while it has solved the problem of furnishing the necessary help during the summer months, it has resulted in driving out the native farm laborers, who have been unwilling to compete with the season workers, and they have gone into other industries or moved away, so that during the remainder of

the year there is a scarcity of farm labor.

To an American it is repugnant to see thirty or forty women working in a beet field under a man boss, but when he raises any question as to the fitness of it, he is quickly told that it is better for them than working in American factories in our large cities. Perhaps it is, because for the most part they are young, strong Bohemian and Polish women who seem to have as much physical strength as a man But it is all contrary to the American conception of the sphere of woman, and if sugar beet culture cannot succeed in America without the general adoption of the use of women laborers, it is not likely to make any great progress, and we shall continue to import our sugar.

Germany's Gain in Exporting Sugar.

Germany, with its annual export of 800,000 to 1,000,000 tons of sugar, worth $50,000,000, is gaining not only that volume of international trade, but is not losing a penny's worth of plant food from the soil, because sugar is nothing but sunshine, water and carbon dioxide. On the other hand, the United States imports over $100,000,000 of sugar every year, and exports cereals and cereal products to a value of over $130,000,000. These cereals are all rich in the elements of plant food that come from the soil and determine the degree of fertility of the land. These elements, nitrogen, phosphoric acid and potash, have a stable market value at which they are sold in the form of commercial fertilizers It is a simple matter of calculation to determine what it would cost to replace the plant food that we lose each year through our export of cereals and cereal-products, and estimating these on the most conservative basis it amounts to at least $30,000,000

This certainly is wise economics from the standpoint of German agriculture, and so long as Germany can find a market for its sugar, they can well afford to import the grains, mill-feeds and other concentrates, and thus build up their own agriculture, but from the standpoint of the United States, we cannot afford to go on paying out over $100,000,000 per year for sunshine, water and carbon dioxide manufactured into the form of sugar

Germany's Interest in American Beet Sugar.

Since the beginning of the beet sugar industry in America, Germany has watched its development anxiously Many investigations have been made of it, and as much or more has been published in Germany concerning it as in America. The consensus of opinion here seems to be that the one great obstacle to sugar beet production in America is the labor problem The fact that America does not have the cheap labor of Europe, and especially that women are not used as field laborers, the Germans think is sufficient to keep the United States from becoming any serious competitor But notwithstanding these handicaps, and the fact that the beet sugar industry has only been established in the United States about twenty years, we already produce one fourth as much beet sugar as Germany, and the production is constantly increasing.

The United States uses more sugar than any other nation, and although only two other nations surpass it in the amount produced, Germany and Russia, it is still necessary to import more sugar than any other country in order to supply our needs. Last year the importations amounted to over two million tons, and in addition to this one and one half million tons were produced within our borders, including Hawaii and Porto Rico, approximately one million tons being produced from sugar cane and one half million from sugar beets.

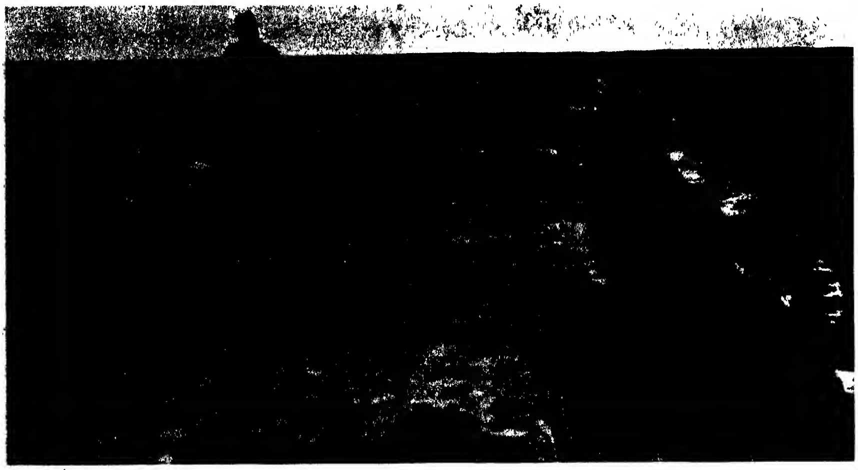
We may increase our sugar production as much as the total production of Germany at the present time, and we will only be producing enough to supply our own consumption. Surely as far as the United States is concerned there is no great danger of lacking a market for all the sugar we may produce.

SIXTY-EIGHTH YEAR

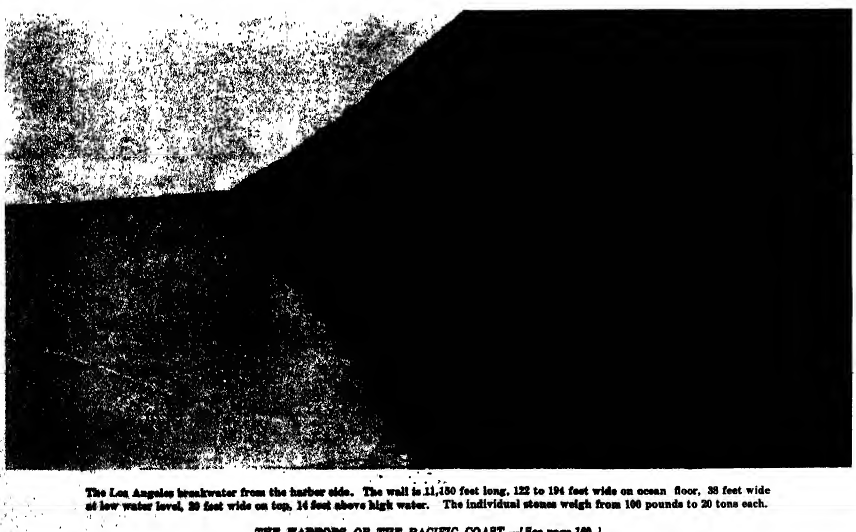
SCIENTIFIC AMERICAN

THE WEEKLY JOURNAL OF PRACTICAL INFORMATION

VOLUME CVII. NUMBER 8.] NEW YORK, AUGUST 24, 1912 [10 CENTS A COPY $3.00 A YEAR



The sum of $2,900,000 was spent in constructing 9,250 feet of the Los Angeles breakwater. The mass of stone used weighs 2,420,337 tons. The breakwater creates an outer harbor of refuge, 375 acres in extent.



The Los Angeles breakwater from the harbor side. The wall is 11,150 feet long, 122 to 194 feet wide on ocean floor, 38 feet wide at low water level, 20 feet wide on top, 14 feet above high water. The individual stones weigh from 100 pounds to 20 tons each.

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are *sharp*, the articles *short*, and the facts *authentic*, the contributions will receive special attention. Accepted articles will be paid for at regular space rates.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

Railway Speed and Safety

THE Public Service Commission, after investigating the recent wreck of the Twentieth Century Limited, found that the accident was due to the breaking of a rail, and that, though the rail was a fairly good one, it was not equal to the strain to which it was subjected under the high speed of this famous train. According to the report, the fastest express trains are running on "schedules too fast for safety;" and the commission recommends that the speed should be reduced with a view to easing up the burden which is now imposed upon the tracks. In other words, instead of bringing the rails up to the speed, it is suggested that the speed be brought down to the rails.

Now, this means that the rail manufacturers are to be put in control of the whole situation; they are to manufacture the kind of rail which suits their particular whim, and then the speed is to be adjusted to whatever kind of product they care to turn out. Put in plain words, that is the exact situation; and if ever there was a case of deliberate retrogression, it is to be found in this proposal to reduce speed. We are not for a moment disputing the broad wisdom of the suggestion made by the commission. On the contrary, we believe that the commission is correct in its statement that the present speeds are too high for the kind of rails over which it is being made. Until an absolutely reliable rail is produced, it would certainly be desirable to ease up on the heavy strain to which the present rails are exposed, when the enormous engines which haul our fastest trains run at speeds of from sixty to eighty miles an hour.

In the choice between high speed and good rails, however, it is assuming too much to suppose that it is impossible to produce a rail which will stand up under heavy, high-speed traffic. On the contrary, it is well understood by engineers that it is possible to produce such rails, and that the failure to secure them is entirely due to the rail makers. More than once, the SCIENTIFIC AMERICAN has gone deeply into this question, and we have shown that the deterioration in steel rails is due entirely to the reluctance of the rail mills to discard a sufficient percentage of the steel ingot, and to put into the rolling of the rail in the mills that time, care and patience, which are necessary to secure an absolutely reliable product. When the steel has been cast into an ingot, preparatory to rolling it down into rails, a large percentage of the steel is defective. Conscientious manufacture demands that the whole of this defective portion be cut away, and only the sound portion be sent on for heating and rolling. The engineers of the railroads, anxious to secure rails free from "pipes" (hidden, incipient fractures in the rails) demand a large percentage of "discard" as it is called, asking sometimes for as much as twenty-five per cent; but the manufacturers, aiming at economy of time and labor, a cheap product, and large output, have always contested this demand of the engineers, and have made the discards just as small as they possibly dare to do.

So powerful has been the influence of the manufacturers, many of whom are directly interested in, and more or less control, the railroads, that they have continued to send out an inferior rail, and the result has been shown in the large number of accidents in the past few years, that are attributable to rails which have broken because of incipient pipes or fractures, hidden within the rails.

The Public Service Commission is in favor of high speed under proper conditions; but it begins to look as though it realizes how all-powerful is the influence of the manufacturers, and, therefore, despairing of a sufficiently good rail, the commission has taken the only course open to secure safe travel, and has recommended that speed be reduced.

But high speed, under proper conditions, is one of the ear-marks of progress; and it is too early in the day to acknowledge defeat and accept whatever the manufacturers are pleased to offer. A redesigning of the rail section, a better distribution of the metal in the various parts of the rail—head, web or base—a twenty to twenty-five per cent discard of the ingot, and a showing down of the rail mills to a speed which would insure a high quality in the steel, would give to the country a rail over which fast trains could run at high speed, without danger of derailment.

First Fruits of the "Titanic" Disaster

THE White Star Company, is to be commended for the promptitude with which it is putting into practice the lessons taught by the "Titanic" disaster. According to cable dispatches, the company is making radical changes in the underwater construction of its two largest vessels, the "Gigantic" and the "Olympic." The extensive and costly nature of this work may be judged from the fact that the total expense is given as approximately a million and a half dollars. The outlay is large; but we believe that it will be more than compensated by the increased confidence of the public—a confidence which was rudely shaken by the sudden loss of the latest and finest of the ships that fly the White Star flag. For the past fifty years the White Star ships have been regarded (and very justly so) as among the most substantially constructed and best officered of the trans-Atlantic liners. The recent disaster was chargeable more to the system under which modern ships have been built and operated than to any particular delinquency on the part of the company, whose vessel happened by the laws of chance to be the one selected to demonstrate how faulty that system was.

Therefore, the prompt action of this famous line in taking steps to render its ships proof against such an accident as befell the "Titanic," is certain to restore confidence in the White Star Line and lead the way in a return to those principles of safe construction from which the art of shipbuilding had so widely departed.

The changes in the "Gigantic," a slightly larger vessel than the "Titanic," were foreshadowed by Mr. Ismay in his testimony before the Senate Investigating Committee. The "Gigantic" is now under construction at the Belfast yards, and the improvements will consist in extending the inner plating of the double bottom up the sides of the ship, to a point well above the deep load water line. We are not in possession of the details; but in all probability this plating will be riveted upon the inner flanges of the heavy web frames, nearly three feet in depth, which extend throughout the greater part of the ship's length. In his testimony before the Lord Mersey investigation in London, Mr. Wilding, the chief naval architect of Messrs. Harland & Wolff, stated that there was an objection against such an inner skin, on the ground that it would be difficult to inspect the inner surfaces of the plating, and serious rusting might occur. The objection would be valid if the space between the skins were too narrow to admit a force of painters. But a width of three feet would give the necessary clearance, and it would be quite possible to provide manholes, of suitable size, through which a gang of men could enter to inspect and repaint the interior surfaces.

The changes to be made in the "Olympic" will be even more extensive and costly. They will involve an entire reconstruction of the boiler rooms. The present transverse bunkers will be removed, and new coal bunkers will be built along the sides of the vessel, the construction being similar to that of the "Mauretania" and other ships of her class. This will involve an entire re-arrangement of the boilers, which at present are placed five abreast, each battery extending entirely across the ship. Probably the boilers will now be placed three abreast, which would leave sufficient room for longitudinal coal bunkers. The inner walls of the bunkers will form practically an inner skin to the ship, and any rupture of the outer skin would involve the flooding of merely the relatively small bunker compartments in the neighborhood of the injury.

The fact that this work has been undertaken by the White Star Company in advance of any legislation making it mandatory, is very significant; and it cannot fail to exert a powerful influence in hastening the forthcoming reforms in the construction of passenger ships. If the changes in the "Olympic" and the "Gigantic" are to be made in association with a watertight steel deck, at or near the water line, it is not too much to say that the fine vessels will be practically unsinkable by any conceivable disaster of the sea.

The Unfortunate Bureau of Chemistry

IF any one who is at all familiar with the present organization of the Bureau of Chemistry and its unscientific methods cherished the illusion that a new and brighter era was to dawn with the appointment of an energetic, competent man to fill Dr. Wiley's place, and that the investigations of the bureau were henceforth to be so conducted that it would be unnecessary to maintain at great expense a Referee Board to check up the work of the Bureau, he is doomed to disappointment.

The Pure Food and Drugs Act, as fine a piece of legislation as Congress ever enacted, is destined to remain ineffective because the head of the Bureau of Chemistry is either unable or unwilling to gather scientific evidence of frauds and to present that evidence in legal form. It is highly probable that the real scientists in the bureau, the men who have conscientiously endeavored by rigorously conducted experiments to ascertain the actual and not the supposed effects of drugs and preservatives in foods and beverages, will resign, leaving behind them a heterogenous collection of alleged analysts and of pseudo-chemists. Not until incompetent officials now in positions of authority have been relegated to places which they are really able to fill, and are prevented from further interfering with the effective administration of the Pure Food and Drugs Act will the Bureau of Chemistry be in a fair way of redeeming its shattered scientific reputation. It is astonishing to us that the press throughout the country has failed to realize how farcical it is to have a Bureau of Chemistry and a Referee Board engaged in exactly the same work, the one vehemently proclaiming its guardianship of the public stomach, the other critically examining the facts by the rigorous methods of scientific reasoning and experiment. In no other branch of the Government service, certainly in no branch in which scientific work is conducted, is this anomaly to be found. The Bureau of Chemistry has the unenviable distinction of requiring supervision from an extraneous body of experts. Like the sophomore class at college, it needs the correction of a faculty; and, as might be expected, conducts itself in a sophomoric way.

The situation must be intolerable to every man of real scientific instincts. Men who have conscientiously endeavored to ascertain whether or not certain ingredients in foods and drugs sold to the public are harmful or not, and who have been bold enough to voice their convictions in reports recommending that manufacturers be permitted to use these ingredients because of their harmless effect, have been treated as rascals. Men with little or no laboratory experience, who have prepared what may be called cooked-up evidence of fraud and toxicity have been praised and advanced, even though the courts have ultimately decided against them.

The daily press has hailed with enthusiasm the appointment as head of the Bureau of Chemistry of a man whose past career holds out no promise for future reform in the methods of administering the Pure Food and Drugs Act. A graduate of an agricultural college in the Middle West, he has never published any scientific work of importance; nor has he pursued any graduate studies. The relation of physiology to the Pure Food Law is a sealed book to him. Far better would it have been if an intelligent civilian with an open mind were appointed.

Alas, for the Pure Food Law! Manufacturers who have money enough to fight in the courts and to engage experts at high market prices will continue to toy with it, and the poor public will continue to alleviate the pains of indigestion, contracted because of the Bureau's ineptitude, with medicines whose sale the Bureau ought to prevent. If "muck-raking" were still journalistically fashionable what a sensation the exposure of the conditions in the Bureau of Chemistry would create!

The International Institute of Agriculture.—M. Louis Dop, the French delegate to the International Institute of Agriculture in Rome, and vice-president of the Institute, has published a pamphlet reviewing the history of this remarkable body, and predicting the lines of its future development. Fifty countries now adhere to the convention of 1905, and contribute a total of $100,000 a year to the maintenance of the Institute; while the King of Italy, from his private means, contributes $60,000, and has given the Institute a splendid building in Rome. Besides the world-wide crop-reporting service—which has been the dominant feature of the enterprise from the beginning—many other lines of work are carried out on a vast scale. Probably one of the most important is the collection and abstracting of agricultural literature from every corner of the world. The voluminous publications issued by the Institute during the last two or three years include, besides its regular periodicals, many exhaustive reports on special subjects, e. g., the crop-reporting systems of the different countries, the organization of agricultural meteorology, statistics of hail insurance, etc., etc.

Electricity

Tungsten Street Lamps in Chicago.—Chicago has decided to substitute 80-watt Tungsten lamps for the gas street lamps it now uses. The gas lamp posts are being remodeled to receive the electric lamp. Over five thousand Tungsten lamps are to be installed.

An Automatic Waiter.—An Australian has invented an electric waiter for hotels and restaurants, operated by the customer seated at his table. A wooden frame holding the menu card is fitted with push buttons opposite each item, and "pressing the button" rings a bell in the kitchen and displays the order and the table number. The kitchen apparatus also prints a check the original of which comes to the customer, with a duplicate on an endless tape. This device has been in successful use in New Zealand.

Vacuum Cleaning Extraordinary.—A machine combining two modern inventions, the electric car and the vacuum cleaning apparatus, has been applied in Strassburg to clean the tramway tracks of that city. In the operation of the machine the roadbed is sprayed with water, then the dirt is loosened by a scratcher and drawn up into the car by the suction apparatus. With this machine one man can clean 25 miles of track a day, replacing the labor of 17 men working in the ordinary way.

Electrical Transmission of Small Water Powers.—The present day is one of very large hydro-electric transmission schemes, but in France small water powers have been successfully utilized. A typical rural hydro-electric scheme is that of Cotentin, on the banks of the river Saire. In this installation the energy in the fall, only 15 to 20 horse-power, is transmitted over a maximum distance of 4½ miles. During the day the output of the generating plant is utilized to run dairy machinery, and at night the current is switched on to lighting circuits.

Flashing Sign for Autotruck.—The large number of electrically propelled trucks now in use has suggested the idea of equipping these trucks with electric flashing signs. This has been tried out and has proved very effective. An automatic flasher is used which will change the color of the sign with each flash. The name or trade-mark is outlined with electric lamps and the sign is flashed out at frequent intervals in red, pink, white and green lights. The effect is very pleasing making the advertisement correspondingly valuable.

Improved Method of Lifting Pig Iron with a Magnet.—It is quite a common practice to use lifting magnets for handling furnace pig iron. Usually the pigs are stacked horizontally and not many of them can be lifted at a time because a relatively small number can be brought into contact with the magnet. Someone has recently hit upon the idea of stacking the pigs vertically, so that the face of the magnet will touch a greater number of pigs. It has been found that by this method, the lifting capacity of a magnet which heretofore was able to raise only 1,000 pounds of pig iron was increased to 2,000 pounds.

Reflecting Power of Wall Papers.—The surface brightness of walls or ceilings lighted by daylight or artificial light is now determined directly by an improved portable apparatus for measuring illumination and known as the "holophane lumeter." Tests of various wall papers in rooms lit by tungsten lamps showed that a surface brightness of 0.3 foot-candles is usually necessary to give the room a cheerful appearance. Light blue, dark red, deep green, and very deep blue wall papers showed surface brightness varying from 0.3 foot-candles for the first mentioned to 0.05 foot-candles for the last mentioned, with corresponding reflecting powers varying from 40 per cent to 4.5 per cent.

Short-haul Electric Truck Service.—An excellent illustration of the value of the electric truck for short haul is cited by the *Electrical Review and Western Electrician*. In a certain large mill a boiler plant is located about a hundred yards from the coal storage yard. The fuel used to be handled by wheelbarrows, but an electric truck salesman learning of this work, made an investigation of its cost and came to the conclusion it could be done more economically by the use of a motor-driven truck. A storage battery truck was purchased and it soon proved its economy. A single man was required to operate the truck, his work including the loading as well as the discharge of the truck.

Hand-driven Generator for Wireless Telegraphy.—The United States Signal Corps has developed a new form of generator for use with its portable wireless telegraph sets. It consists of a small generator, the rotor of which is driven by hand cranks through a suitable gearing. Two cranks are provided, so that two men may drive the motor at the same time, and if necessary four men may be employed—two at each handle. A low and high speed release is provided, which disengage the driving gear when the speed rises above or falls below a predetermined limit, so that the rotor may be kept at a fairly constant speed. The generator is capable of turning out about 200 watts, and it is light enough to be packed on a mule. The portable generating set has a sending capacity of about fifteen miles.

Science

Cape Deshnef.—The extreme northeastern corner of Asia is still called "East Cape" in many atlases and other geographical works. The *Bulletin* of the American Geographical Society calls attention to the fact that the name of this point was changed to "Cape Deshnef" in 1898 by command of the Emperor of Russia, in honor of the explorer who discovered it.

Surveying with the Camera.—The first extensive use of the panoramic camera to supplement the plane-table in surveying is said to have been that made by Mr. J. W. Bagley, of the U. S. Geological Survey, in mapping an area of 160 square miles around Valdez, Alaska, during the season of 1911. This method promises to become a regular feature of the Survey's work in Alaska.

The Twelfth International Congress of Geologists met at Toronto, Canada this week. Among the special subjects for discussion were the world's coal supply, and interglacial periods. Twelve excursions of from one to twelve days took place before the meeting, and ten of from four to twenty-three days after it; some of the latter extending to the Pacific Ocean and the Klondike.

Fixing Atmospheric Nitrogen in Iceland.—Thorlakhavn, the best natural harbor on the south coast of Iceland, has been acquired by a French company, along with neighboring waterfalls yielding about 200,000 horse-power, and a plant will be erected at this place for manufacturing artificial saltpeter by the utilization of atmospheric nitrogen, according to the Birkeland-Eyde process.

Numbering Street Car Lines.—The names of street car lines are usually a source of perplexity to new arrivals in a city, and the confusion is often increased rather than mitigated by the signs on the cars. A consular report from Amsterdam tells us that in that city the convenient plan has been adopted of giving each car line a number. This number is suspended between the arms of the trolley pole on each car and is visible several hundred yards away. The numbers are always referred to in directing inquirers. Most German cities have a similar system, which works very successfully.

A Rhine Museum is soon to be founded at Koblenz, if present plans are carried out. It will include a large collection of charts, pictures, models and diagrams illustrating the physical conditions, past and present, of the famous river, and a complete exposition of its economic history. Some of the unique features will be: Models of the various types of vessel used on the Rhine from early times to the present; models of past and present bridges; illustrations of the methods and apparatus used in maintaining and improving the navigability of the river. A fine series of geological models is contemplated. The city of Koblenz has already given a site for the building.

Spitsbergen as a Scientific Preserve.—Diplomatic negotiations regarding Spitzbergen, now in progress, contemplate the unique plan of setting aside this far northern archipelago as a sort of happy hunting ground for scientific men. According to this plan, no land can hereafter be acquired in Spitzbergen except for purely scientific or humanitarian purposes, and the further exploitation of land already in the possession of commercial organizations (mines, fisheries, etc.) will be placed under such restrictions as will ensure the preservation of the flora and fauna. The hunting of fox, polar bear, walrus and reindeer will be prohibited from May 1st to September 15th. The hunting of elder-duck will be prohibited entirely, as also the use of poisons and explosives in fishing.

The Pittsburgh Smoke Investigation.—The Department of Industrial Research at the University of Pittsburgh has published the first of a series of bulletins on the investigation of the "smoke nuisance," for which funds were provided on a munificent scale by a Pittsburgh business man. The investigation is being carried on by a staff of twenty-five specialists, six of whom give their entire time to the work, while the others have been intrusted with the preparation of reports on special phases of the subject. The topics discussed briefly in the initial bulletin are: Smoke and the Weather; How is Vegetation Affected by Smoke and Soot; The Chemistry of Smoke and Soot; The Physical Problems of Smoke; Deterioration of Buildings and Building Materials; Smoke and Disease; What the Smoke Nuisance Costs; Who Makes the Smoke; Laws and Ordinances Concerning Smoke; General Experimental Work; Smoke Means Waste and Inefficiency; The Education of the Public; The Question of Legal Regulation. It is stated that the smoke nuisance costs Cleveland $6,000,000, Cincinnati $8,000,000, and Chicago $50,000,000 a year, and the whole country over $500,000,000 a year, in damage done to merchandise, defacement of buildings, tarnishing of metals, injury to human and plant life, increased cost of housekeeping, and losses to manufacturers due to imperfect combustion of coal.

Automobiles

$80,000,000 Invested in Electric Vehicles.—According to statistics collected by T. C. Martin, chairman of the committee on progress to the National Electric Light Convention at Seattle, recently, there are at present invested no less than $80,000,000 in electric vehicles, of which sum about $25,000,000 represents the outlay for trucks and delivery vehicles, and $55,000,000 the value of pleasure cars.

Huge Racing Car Coming.—A specially built, 300 horse-power Benz racing car soon will make its appearance in America. The car is said to have been purchased by a well-known race promoter and will probably be driven by Robert Burman, holder of the world's record for straight-away speeding, in an endeavor to lower his own record of 25 seconds for the mile. The car is reported to have made a mile in 21 seconds, or almost three miles a minute.

Yellowstone Park and Automobiles.—Representative Rucker has petitioned the United States Government to open Yellowstone Park to automobiles. This famous park is still closed to motorists, and it is claimed that there is no valid reason why it should remain so. The present-day automobile is a different thing from the unreliable noisy contraption which was excluded from the park years ago. There appears to be a growing disposition on the part of those responsible to open the park to tourists and their motor cars.

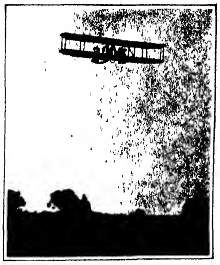
Motorist Poisons Fish by Carbide.—An American tourist had a peculiar experience recently in Southern Bavaria. Passing by a small stream, after a long trip, he stopped his car to empty the old carbide from his acetylene generator and refill it. A few days later he received a note from the supervisor of the county, notifying him of a suit for damages entered against him for poisoning the fish in the river with carbide. It seems that the part of the river had just been stocked with bass, and many had been killed by the gases developed by the carbide residue.

London Introduces "Reversible Omnibus."—Because of the narrow streets in several parts of the city of London it has been found impossible to use the ordinary motor omnibus on account of its comparative length and the attending difficulties of turning the bus around at the end of a trip. Some of the routes laid out for the motor buses are circular, thereby obviating the necessity for making complete turns. On some occasions it has been found impossible to map out circular routes, and a new type of bus is being tried out, which is reversible, the same as a trolley car. It can be steered from either end, conductor and driver simply changing places.

University Establishes Automobile Science Course.—The first university in this country to recognize the importance of the motor car and to place it on an equal footing with the building of bridges, railroads and tunnels, with chemistry and other sciences, is the University of Southern California. The new course is for the benefit of automobile mechanics, engineers and designers, and the first professor of automobile science is Stanley Smith, C.E., who has just been appointed to the chair. While he will deliver lectures on the various subjects properly belonging to automobile science, he will specialize on motors and their efficiency, sliding, poppet and rotary valve types, etc.

Military Exemption for French Motorists.—For the purpose of facilitating the transportation of the general staff in case of war, the French military authorities have decided to give those who own cars of medium horse-power, and who are able to prove their ability of driving them and taking care of them as far as tires and ordinary road repairs are concerned, a special opportunity to discharge their military duties in an agreeable manner. Instead of being compelled to drill with the other conscripts, such owners must sign an agreement with the authorities that they will turn over to the government immediately following mobilization the vehicles described in their application for this sort of service. At all maneuvers the car must be at the service of the military authorities, to be driven by the owner himself under orders from the officers.

Mysterious Fire from Odd Cause.—A German motorist the other day discovered the most extraordinary cause of a fire starting in the carbureter of his automobile that has ever been brought to public notice. Noticing a leak in his carbureter connections, he stopped the car in a completely deserted road in full sunlight. There was no spark, fire, match, broken insulation, or any other thing that could possibly have caused the gasoline to catch fire; yet in a few moments the carbureter was ablaze. Luckily the motorist was something of a scientist and he started on an investigation of the "why and wherefore"—after he had managed to extinguish the fire. To his surprise he discovered that the catch on the convex front lens of the headlight had become unfastened and the lens had swung around in such a manner that the sun's rays became focused directly on the leaky connection at the carbureter; a highly effective burning glass being thus responsible for the "inexplicable" blaze.



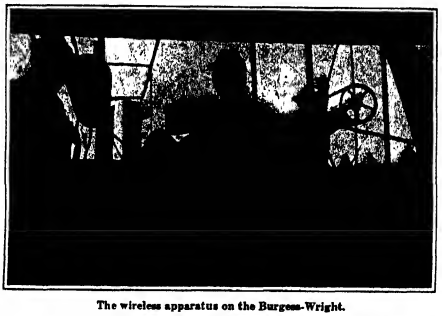
The Burgess-Wright off on a reconnaissance.

The Aeroplane in the Military Maneuvers

The War Operations in Connecticut Clearly Point to the Necessity of Having a Large Well Trained Corps of Aerial Scouts in Our Army, Equipped With Machines Capable of Rising from Unfavorable Ground With Two or More Occupants

Lieuts. Milling and Foulois in the Curtiss machine.

NO doubt the most important feature of the mimic war in the hills of Connecticut has been the scouting of the aviation squadron. This is the first time that aeroplanes have played an important part in any military maneuvers in this country, and their work has been exceedingly gratifying. After the region in which it was decided to hold the maneuver had been selected, it was gone over very carefully to find a suitable field from which the movements of the troops could be directed and where the aeroplane squadron could have its headquarters. In this entire territory of 240 square miles, only one spot was found where there was a stretch of three hundred yards practically level and untimbered. Here the headquarters was established and the field was prepared to permit of launching aeroplanes. The engineering corps worked for a day dynamiting the rocks and succeeded in clearing one hundred and fifty yards near the southern end of the field. To the south of the field was a heavily wooded tract, while the north end was closed by a low stone wall. The field was so narrow that the aviators were compelled to start always toward the north regardless of the direction of the wind. This made it particularly difficult because the prevailing winds were at the back of the aviators. Owing to these conditions it was next to impossible to launch a machine with two passengers. In the aviation squad, there were two machines belonging to the regulars and one machine of the New York National Guards. The latter was a Curtiss machine, piloted by Private B. Havens. It was equipped with a 75 horse-power engine, but its wing spread was not great enough to permit of launching the aeroplane under the unfavorable conditions with a passenger. Consequently, the pilot had to go aloft alone and make his own observations. Not being a trained scout, he found great difficulty in observing the armies, and could not distinguish between the various bodies. The Curtiss machine of the United States Army was piloted by First Lieut. T. DeW. Milling of the Fifteenth Cavalry. This machine was also found to have too small a wing spread to lift two men off the ground from the field at Paradise Green. The attempt was made at one time and it came very near to resulting disastrously. With Lieut. Milling was the lightest member of the aviation squad, Lieut. Geiger. The wind behind the aeroplane drove the machine along so rapidly that it reached the end of the field before it could lift itself more than a few feet off the ground. Both occupants of the machine thought that they were doomed, but they succeeded in just clearing the three-foot stone wall by a few inches. They also narrowly escaped collision with the woods at the end of the next field. So narrow was their escape that it was decided to make no further attempt at carrying a passenger until wing extensions could be secured.



The wireless apparatus on the Burgess-Wright.
Note the telegraph key at the extreme right of the picture.

Curtiss aeroplane clearing the stone-wall

The other regular army machine is a Burgess-Wright. Although furnished with an engine of but 50 horse-power, and capable of making but forty miles per hour, this machine had no difficulty in rising from the field. But Pilot Lieut. B. D. Foulois had equipped it with a wireless telegraph apparatus, the weight and disposition of which made it impossible to carry a passenger. Two other machines which were to have been on hand for the maneuvers were injured on their way to the field. One of these, a hydro-aeroplane, was wrecked in Plymouth Harbor. This was very unfortunate because there would have been a good opportunity to launch a machine from any desired point on the Housatonic River against the wind, regardless of the direction in which it was blowing, and with a passenger, the observations made would undoubtedly have been much more complete than was possible with the pilot flying alone.

During the first half of the maneuvers the aeroplane squadron was neutral, and was required to report the position and movements of troops on both sides. A problem would be assigned to the aviation squadron requiring it to make a reconnaissance as soon after dawn on the next day as practicable, covering a fixed territory usually a triangle, the points of which were given. The instructions were made somewhat ambiguous, so as to test the intelligence of the men. For instance, on August 12th the order was given that "the triangle, Stratford, Derby, and Long Hill, be examined for the location, composition, and strength of the military forces covered therein, results being reported at headquarters, as soon as practicable." On up to midnight the squadron pored over the map, studying carefully the territory and trying to make mental pictures of it. It was found that there were two Long Hills, but one of them was eliminated, because it lay practically in a line with the other two points. It was assumed, therefore, that the other Long Hill must be the one referred to, even though it was not so prominent on the map. Their reasoning proved correct.

The aviation regulations required that they carry registering barographs and wrist aneroids. They were required to fly

Teaching the Farmer How to Use Electricity

A Circus Tent Display of Farm Apparatus by a Central Station Company

By Thomas Commerford Martin

FOR some years past the machinists and electrical manufacturers of the country have been going through an elaborate process of adapting the machine tool and the electric motor to each other, whether for belt or for direct drive; and the development in this important field of industry may at last be regarded as fairly complete; for there is literally no art into which electric power has not now made its way. Indeed, in many branches of production it is already the leading source of energy. This chapter of electrical history succeeded that of the trolley, which in turn devolved from the electric lighting period; and the results of all these epochs are to-day converging upon the efforts that electricity is making to win for itself one of the oldest domains of human endeavor—agriculture. Thanks to the ever-progressive policy of this journal, the readers of the SCIENTIFIC AMERICAN have been made aware of the remarkable advances effected lately in rural districts by electric light, heat, power, and traction, and will also have noted that after all the work has but barely begun, leaving still an infinite opportunity for the engineer, the inventor and the farmer. It is certainly significant of coming changes that this year the subject has been formally presented to the United States Department of Agriculture for study; that the United States Bureau of the Census is seriously considering making it a special part of the electrical census of 1912; and that both the American Institute of Electrical Engineers and the National Electric Light Association are making it the topic of frequent papers and committee reports.

All this new interest, stimulated of course by the high cost of living, the "back to the farm" sentiment, and the greater wealth of rural communities, has been due largely to the fact that the new power transmission systems, looking for a market for their current, are themselves unavoidably throwing a network of circuits over vast agricultural regions, so that in reality the market sought lies immediately around them. Relatively few farmers can afford to put in generating plants of their own, but when the aerial tracks for lighting supply run right by their doors, it is easy and cheap to tap them for even a very small local consumption. This is what is now going on over large areas particularly in the West and on the Pacific Coast, but there is another extremely interesting aspect of the matter to which the present article draws attention. The city central station systems once limited to small urban districts have expanded into the outlying regions to such a degree that where they formerly served but a few square miles of territory they now embrace hundreds. Thus the North Shore lines forming an outer ring to the Chicago system with which they are "tied in," are already supplying electricity in a region of 1,200 square miles with seventy-one towns and villages, and the old Boston Edison Company, not long ago centered tightly around the famous Tea Wharf, operates actively in a principality not far short of 700 square miles. This district, while very populous, is also decidedly rural, with heaven alone knows how many farms and market gardens in it, and hence we find the company, in a highly original way, making a strong play for the farmer's patronage. Within Boston it has been spending over $100,000 a year in publicity to exploit the electric vehicle, and now with protean versatility, it is spending probably an equal sum in trying to electrify the countryside. Such enterprise and ingenuity as are being displayed would seem likely to enjoy a rich reward; at any rate it is only in this manner that the thing can be given a real test.

One of the great problems, of course, in introducing

The wood splitter in operation.

electrical farm apparatus is that of reaching the prospective customer, rather remote from factories and stores and hard to convince by even the cleverest advertising and literature The "prospect" has got to be shown that it is to his benefit to adopt the innovation, and even then will be loathe to invest. In one or two sections of the country the electric power company has aimed to meet the question by buying a farm in the heart of a likely district and operating it on an electrical basis, so that the neighboring folk can see for themselves how it works out. This is a slow method, and, besides, very often a farmer does not want, or need, to electrify his whole farm, but prefers to get some special appliance of a particular make. The plan of the Boston Edison Company has, therefore, been to invade its rural territories with a live demonstration, and to move the show from place to place, so that the whole population within the belt—say 750,000 people—can be convinced, the old farmers converted, and lots of citizens hungry for farm life shown that it is feasible for them, shorn of its wonted drudgery.

It is thus a traveling circus that the company has in operation, and the novelty of that feature alone helps to attract visitors The number of practically interested people inspecting it has averaged about 100 a day right along, to say nothing of any number of persons and children lured by mere curiosity; but even they are not to be despised With an occasional band of music and the regular pink lemonade concomitants, the "Circus Farm," when in full operation is a fair rival of the sawdust ring as an amusement, altogether aside from the fact that it is giving instruction, and has already set the wits working of many a shrewd and inventive observer, who sees at once that here are new ideas and phenomena in the shaping of which he may play a part, as applied to the greatest and oldest industries The Circus Farm is a big canvas tent, 60 by 100 feet, under which is housed a grouping of some forty large pieces of apparatus and farming tools, supplemented by thirty or forty ordinary and smaller appliances. All the apparatus is ready for use, and runs, and demonstrates its economic service on the farm. Each appliance is plainly marked with its name, the manufacturer, its price, and the cost of operation. The price is retail and includes the machine, its motor and everything ready for actual service on the farm. Some machines and tools have been omitted from the exhibition because they have been regarded as unpracticable—at least for use in New England territory. Others are not shown because it has not been possible to "standardise" them, that is, furnish them to the purchaser with "everything all on" ready for operation.

For the first five weeks the farm was located on the Old Middlesex South Fair Grounds in suburban South Framingham, easily reached by the electric car lines The main poles of the tent are surmounted with pennants, and in front of the main entrance have been placed three large canvas display signs in striking colors to add some of the "drawing" effect of a high-class circus. The scheme has proved effective. A broad, main passageway extends down the center of the tent from end to end On either side are the working exhibits protected from the visiting throng by railings. The tent is brilliantly lighted at night with 500 watt incandescent lamps, and the outside grounds are made brilliant with luminous arcs.

Two electric trucks, one of two-ton capacity and another of 700-pound capacity, are used in connection with the farm for hauling material to and fro. A special feature of the truck service has been in demonstrations to the neighboring farmers. Wherever the farmers have shown an interest in the truck proposition, the vehicle suited to the service has been sent out to haul loads around on the farm. From time to time material has been carried from farms into town, or *vice versa* The result has been that many of the farmers have now practical knowledge of the working efficiency of an electric truck on the farm, and are considering its adoption

The farm is equipped with a motor on a portable truck, which can be moved from place to place and connected up with any piece of apparatus This shows, of course, the practicability of portable electric power on the farm.

The milking tests prove very attractive to the people, and there is always a crowd at the evening milking time. Practical milking demonstrations have been given at large nearby dairy farms, to the great satisfaction of dairymen. The farm is resulting in excellent business, and many of the purchases of electric appliances are traceable directly to the inspiration and information gained there.

Obviously, there were many incidental difficulties in carrying out this ingenious scheme, but with a supply of power always at hand from its own circuits, the company has been able to meet them Like all circuses moving from point to point, the question of transportation has to be dealt with, but here the electric truck has a great chance to prove itself under genuine country conditions. In order to keep the circus going steadily, the company has two tents, so that the next site can be selected and one tent set up before the existing circus is moved on and the other tent taken down. Hence, the apparatus has its home awaiting it, is protected from undue exposure, and can at once hitch to the waiting circuits.

In addition to this "Circus" or "County Fair" of its own, the Boston Edison Company has worked out a kindred idea in its "Edison House," which aims to show the farmer or the suburbanite how electricity can also be utilized indoors as well as out. This model dwelling is portable, and is moved from village to village, being set up in each place with appropriate and pretty floral surroundings. It is always put in charge of some local woman of intelligence, and all the women's sewing bees and local clubs can make use of it—which they do freely. Kitchen, living room, cellar, dining room, bedroom, porch, woodshed, are all equipped thoroughly, and it is difficult to think of any domestic operation that is not here shown under full electrical conditions. It is inevitable that such missionary work should tell in the long run, and that in this way, with the aid of electricity, the farmer's life will be made more endurable, more inviting, more profitable. Edison has said that hoeing corn is, from his experience, one reason why large cities exist. Here are reasons why people will not go back to the farm, because they will never leave it.

A Forest Service Circular on Quebracho Wood

IN response to frequent requests received by the United States Forest Service for information relative to quebracho wood, its uses and substitutes, a short circular has been prepared. Quebracho, an Argentine wood, is very important for the tannin it contains and a need is keenly felt for fuller information regarding it, based upon a scientific study of its structural characters. In general appearance the wood is scarcely distinguishable from two other Argentine woods called white quebracho and red quebracho, which yield tannin in a much smaller quantity. A study of the chief distinguishing characters of true quebracho and these two possible substitutes will prove very helpful in detecting the inferior kinds when they are mixed in with the genuine.

The indiscriminate use of the name quebracho has resulted in much confusion, which called for a discussion in order to clear up the nomenclature of the different woods referred to under this vernacular name. The circular is not a treatise descriptive of the many species of tropical and subtropical woods now known as quebracho, but it is devoted chiefly to a discussion of the distribution, supply, uses, and importation of true quebracho into the United States. Perhaps the most valuable portion of the circular is a clear detailed statement as to how the true quebracho can be distinguished from its substitutes. In a discussion of this kind so many unfamiliar terms are generally employed that the lay reader will not be attracted. The aim of the authors has been to substitute the simplest terms in the discussion of those parts of the wood and its uses which are most likely to be of interest and importance to the general reader and the user of quebracho wood. In this the authors have been successful and the subject is treated in an untechnical and popular, yet accurate, manner.

This study on the structural characters of true quebracho and the spurious kinds, affords an interesting illustration as to how apparently similar woods may be easily distinguished by means of a simple pocket magnifier or a compound microscope. Well selected photographs of magnified transverse and longitudinal sections have been included for the purpose of illustrating more clearly in what respects these woods differ.

Uses for Useless Metals

AN immense fortune, according to economic geologists, awaits the man who can invent a use for tellurium. This mineral is one of the by-products of copper refineries and of plants working up gold telluride ores. At present it is all thrown away, as it is absolutely no good to anybody. Only a few years ago tungsten was in very much the same position as tellurium is now. Then it was found to be highly useful in the manufacture of incandescent lamps and tool steel, till to-day it would seem probable that with a cheaper supply it will become one of our most important minor metals. Selenium is another substance which has just come into its own. Up to a year or two ago no commercially important use for selenium was known, although for some three or four years it was one of the ingredients entering into a secret process in the glass industry. It is now well known among scientists that selenium is an agent in coloring glass red, and in decolorizing glass by the use of small amounts to neutralize the green of ferrous iron. A French scientist has also utilized it in an invention by which pictures may be transmitted by wire. Like tellurium, selenium is a by-product derived from the refining of copper. Apparently about twenty tons a year are now utilized commercially.

The Automatic Word-maker

THE blunders of an inexpert typewriter, regarded as blunders merely, do not at first sight, offer much scope for agreeable meditation, either to their perpetrator or to other people. But regarded as phenomena, physical and mental, they are found to be not only interesting matter for study, but valuable contributions to science and scholarship. For, instead of being the mere accidents of careless or awkward fingers, they are really the product of psychological law, and the creators of a new vocabulary.

There is, for instance, the propensity to write a letter twice over. The finger receives an order to touch a certain key, and responds with twice the service called for; like the genial converser of whom Emerson speaks, who, when he has said a good thing, straightway says it over again.

A modification of the same action is that of following a capital with the corresponding small letter, as *Ccork, Rrome.* One wonders if Aaron, Lloyd and their like might have originated in an analogous way.

Again, when a double letter is called for, the order often seems to have been misunderstood, and the wrong letter is doubled, as *lokk* for look, or *feel* for fail.

Still more singular is the tendency to anticipate in one word a letter belonging in the next, as *lask week* for last week.

The most surprising and amusing effects of all are those produced with machines having "shift-keys" for capitals and figures, when one pushes the wrong lever, and having rattled off what he believed to be the word EDUCATION, sees in its place 3?7?&589, or, intending to date a letter 1910, reads QOQP.

In all these blunders except the last it is easy to detect the principle of the time-element in volition. The operator usually foresees the mistake before it is made, but is unable to prevent it. He knows that he has directed the finger toward the wrong key; but he is unable to recall the order and issue the correct one in its place in time to prevent the result. The finger persists in its course in defiance of its owner's will, finds the key to which he had originally directed it, and prints the obnoxious letter in spite of him. This is one of the commonest and most surprising of his experiences. It is also one of the most interesting from a psychological point of view.

But the psychological result is not the only one accruing from this process. The verbal product is also striking and significant. Along with all this irregular and seemingly haphazard mental action, there emerges an original vocabulary, surprisingly copious and interesting. The typewriter is a prolific creator of new words. Besides the frequent substitution of one regular dictionary word for another, and the production of confused combinations that are not words at all, it turns out a multitude of words that are well formed, pronounceable, and even euphoneous, but which no lexicographer ever heard of

The writer has for many years been in the habit of setting down these machine-made words, as they spelled themselves out under his eyes, until there has accumulated a vocabulary large enough to furnish some new-born nation with the nucleus of a language. From between two and three hundred that have been preserved, not one of them intentionally produced, the following one hundred will serve as examples;

ablo	dera	het	neen	seem
actice	dinf	huse	newa	sporn
af	efaf	ir	nive	stry
agarm	epon	id	ond	stang
ang	ew	ite	ot	stoet
aming	ferly	impuse	ovet	suss
agice	fing	inti	parton	tere
aspa	firat	jud	persol	thar
attan	fird	kint	poan	trem
bak	firt	kep	privare	trult
begil	foing	leace	ract	ud
bereen	fot	libarm	repor	urd
bome	fron	lokk	rhe	vety
cance	gollen	lond	ruter	walg
ciré	geom	manf	savoof	wam
conse	greer	mete	scrim	waw
cre	hace	minf	sevond	whid
deat	hald	mosy	serim	whix
depene	havet	mu	shoy	yont
detiture	hels	ned	sme	yoy

This is but part of the product of a single typewriter, not very constantly used. Every one of these words, and hundreds besides, were absolutely accidental. Many of them were produced several times over, from seven times, and id and ir five times each. Could we add to the list the product of the myriads of other machines, each, no doubt, despite the skill of the most expert operators, more or less prolific of similar creations, we should have material for a new unabridged dictionary and a new language.

A machine for the production of a set of new ideas to fit these unappropriated terms is next in order.

Paraffine for the Obstinate Collar Button

To the Editor of the SCIENTIFIC AMERICAN:

In re collar fastenings, the present collar button works perfectly well if the back of the buttonhole is rubbed with paraffine. A pin, too, if rubbed with paraffine, passes through starched linen "like greased lightning through a barberry bush." W. S. B.

Geneseo, N. Y.

A Card Trick

To the Editor of the SCIENTIFIC AMERICAN:

This is an old favorite this side. It was taught me by an old cavalryman more than fifty years ago. His formula was: "Eight kings threatened to save nine fair queens for one sick knave." This, in my experience, rather more mystifies the beholders than that of "Regular Reader," on page fifty-five of your issue of July 20th.

London, W. C. E. J. KIBBANVITE,
Editor English Mechanic.

An Engineer's View of the Patent Bills

To the Editor of the SCIENTIFIC AMERICAN:

Please allow me to thank you, as an inventor, for the splendid article in issue of August 3rd, 1912, regarding the Oldfield Patent Bill. If you only knew how many inventors need a champion like you I am sure you would feel well repaid. The plain words you use should appeal even to a Congressman. The Government is a plain swindler when it grants us the exclusive right to make, use and vend our inventions, after taking our money, as it does not attempt to make its word good. CLAUDE L. HAGEN.

San Francisco, Cal.

The Automatic Stop on Railroads

To the Editor of the SCIENTIFIC AMERICAN:

The recent disastrous wreck on the Lackawanna at Gibson seems to be only another of the already many and gruesome arguments in favor of the adoption of some form of automatic stop in connection with the block signals. Under present conditions the mere fact that a signal does its work properly is no guarantee that the danger will be avoided, since so much is left to the "human element." Rain, sleet, snow and fog are factors to be considered and have time and again proved the inadequacy of even the most perfect block system. The automatic stop is not new, having been tried and found successful under certain conditions of city traffic, and its general adoption for main line railroad work would not only be an added safeguard to passengers, but moreover would undoubtedly pay for itself in reducing such costly accidents as the recent Fourth of July wreck.

This letter is written in the hope that you will take up in your editorials the question of automatic stops, a measure which seems to be only too urgently needed under the present conditions of fast passenger service.

Sangerfield, N. Y. WILLIAM CARY SANGER, JR.

[This matter formed the subject of an editorial in our issue of July 20th.—EDITOR.]

The Nut Problem

To the Editor of the SCIENTIFIC AMERICAN:

General solution for any number of men, n, and any number of monkeys, m, less than n.

Let x = number of nuts in last quotient.

y = number of nuts originally.

It is evident that we can pass from x to y by multiplying x by n, and then performing, n times in succession, a cycle of operations consisting of multiplying by $\frac{n}{n-1}$ and adding m.

Therefore,

$$y = \frac{n^{n+1}}{(n-1)^n}x + m\left(\frac{n}{n-1}\right)^{n-1} + m\left(\frac{n}{n-1}\right)^{n-2} + m \qquad (1)$$

$$= \frac{n^{n+1}}{(n-1)^n}x + m\frac{n^n - (n-1)^n}{(n-1)^{n-1}} \qquad (2)$$

$$= \frac{n^n}{(n-1)^n}\left[nx + m(n-1)\right] - m(n-1) \qquad (3)$$

$\frac{nx + m(n-1)}{(n-1)^n}$ must evidently be integral $= z$, say (4)

n, x, and y are positive integers.

Also, when z is least in value, x and y are least in value.

Substituting from (4) in (3):

$$y = n^n z - m(n-1) \qquad (5)$$

From (4):

$$x = \frac{n-1}{n}\left[z(n-1)^{n-1} - m\right] \qquad (6)$$

Expanding the parenthesis, n divides formally every term except the last two, which, when n is odd, are $z - m$.

The least value for z in this case is $z = m$. (7)

When n is even, the last two terms are $-z - m$. This expression cannot be zero, and must, therefore, contain n at least once, numerically.

Therefore,

$$\frac{-z-m}{n} = -1 \qquad (8)$$

$$\text{or } z = n - m \qquad (9)$$

which is the least value for z when n is even.

Substituting from (7) and (9) in (5):

$$y = n^n m - m(n-1) = m(n^n - n + 1) \qquad (10)$$

when n is odd,

and $$y = n^n(n-m) - m(n-1) \qquad (11)$$

when n is even.

(10) and (11) give the least solutions.

In order to include other solutions, we must evidently add a term of the form pn^{n+1}, where p may have any positive integral value, including zero.

Therefore, the general solution is:

$$y = pn^{n+1} + m(n^n - n + 1) \qquad (12)$$

when n is odd,

and $$y = pn^{n+1} + n^n(n-m) - m(n-1) \qquad (13)$$

when n is even.

Illustrations

In (12) let $p = 0$; $n = 5$; and $m = 1$,

then $5^5 - 5 - 1 = 3{,}121$, the least value, which is the answer to the original problem.

Let $p = 1$

3,121
$5^6 = 15{,}625$

18,746, the next value, etc

For 4 men and 3 monkeys

In (13) let $p = 0$; $n = 4$, $m = 3$

$4^4 \times 1 - 3 \times 3 = 247$, least value

1 4) 247
subtract (61 + 3)
2 4) 183
(45 + 3)
3 4) 135
(33 + 3)
4 4) 99
(24 + 3)
5 4) 72
18

For 10 men and 1 monkey

In (13) let $p = 0$, $n = 10$; $m = 1$.

$10^{10} \times 9 - 9 = 89{,}999{,}999{,}991$, least value.

SUBSCRIBER

Conservation of the Atmosphere.

To the Editor of the SCIENTIFIC AMERICAN:

A recent article in the SCIENTIFIC AMERICAN attracted some attention on the subject of an exhausted atmosphere, or rather, the depletion of the oxygen from the atmosphere. After reading it, the writer asked a college professor if he believed there was a real danger of exhausting the oxygen in the air.

He replied that he guessed that it would last as long as he did

But this reply will not satisfy the scientist, who is weighing things in scales that weigh a hair, nor the philosopher, who reasons long over trifles light as air. This marvelous atmosphere of ours is not a chemical compound, but a mechanical mixture of two gases, oxygen and nitrogen, in the proportions of 20 and 80 per cent, respectively.

The oxygen being the active element, and the nitrogen the diluent or vehicle for the other gas, the normal atmosphere exists in a balanced state, i. e., the loss of oxygen is continually replaced by the plant life, which has the power, in the presence of sunshine, of decomposing the carbonic acid gas produced by respiration of the animal life into its elements, when the green leaves of the plants absorb the carbon for their own tissues, and restore the oxygen to the atmosphere in its original purity.

Carbonic acid is continually added to the air in the various processes of nature, as respiration, combustion, oxidation, fermentation, putrefaction, and so on. Between the processes just mentioned on the one hand, and the absorbent power of plant life on the other, in the normal state a balanced atmosphere is maintained.

In the wisdom of the Creator this action was to be reciprocally maintained until the end of time, but man has disturbed this beautiful balance by introducing new methods and processes ultra-natural

Ergo, new problems are introduced, which must be considered. How long will this equation stand subtraction on the one side without compensation on the other side? The constant loss of oxygen must be felt, and we claim that the grave increase of germ diseases, and their fatal recurrence, the lack of vitalizing power in the air, the marked climatic changes, the droughts, and fluctuations of temperature, and other variations from nature, are results of a steady consumption of the life-giving properties of the air. Of course, this change would be noticed first by trained observers, then more apparent, and finally be obvious to all. The feverish activity of this commercial age is rapidly consuming stores of coal, iron, and timber, that might last for ages

The intense industrial age in which we live is producing an over-balanced condition of the atmosphere, that must surely react in danger, disease, disaster, and death. But what is the remedy?

Suppose there be none! Just suppose that this acceleration go on, what will it culminate in? For example, the ocean speed craze; the intense rivalry that has existed between the three great lines of trans-Atlantic steamers, Cunard, German, and White Star

We know to our sorrow how that has culminated, in the loss of the mighty "Titanic," ramming an iceberg at midnight, under a speed of 21 knots with the awful penalty of 1,600 lives But who pays the penalty? The American people Take the motor car speed mania Faster and faster, sixty, seventy, a hundred miles an hour. But who pays the penalty? The American people

Aviation is the same; he flew, he fell, he died The same story all around. Acceleration beyond the limit of safety Sad, is it not?

I repeat, the people are unbalanced, and so is the atmosphere in which they live. Let someone disprove it, if he can.

But to return to our problem of the air we breathe sixteen times a minute How shall the atmosphere be conserved?

The air in which we live exerts a normal pressure at sea level of 14.73 pounds to the square inch, which is produced by the super-incumbent atmosphere extending up for possibly a hundred miles. Our life is dependent upon the state of this air. It is capable of a certain amount of saturation, expansion, depletion, infection, compression, exhaustion, and restoration.

Let us notice briefly some of the ways in which the air is vitiated.

First, positively, by combustion. Vast tracts of forest timber have burned down annually, and every acre burned must not only be added to the positive side of the equation in the products of combustion, but also be subtracted from the side that furnishes the power of restoration But to the loss of vegetation, by which the carbon dioxide is separated, there is an additional loss of moisture-producing medium to furnish aqueous vapor Where is this loss compensated?

Second, negatively, by loss of aqueous vapor This is essential to health, as the electricity in the body is rapidly dissipated under certain conditions. And disease is induced Saturation beyond a certain point reacts toward depression. Natural balance is maintained by the sun and wind, and evaporation; the air taking up all the moisture it is receptive of, and conveying it over wide areas

Third, absolutely, by depletion or exhaustion, and by infection The cities are filled with air-depleting plants, that exhaust the natural restorative properties of the atmosphere Hundreds of power plants, foundries and furnaces exhaust the oxygen and electric properties of the air, while loading it with the suffocating products of combustion. Smelters consume the vital, and add the lethal.

By infection the air takes up bacteria in dust, and distributes them widely along city streets, and in crowded stores and offices, on trains and otherwise The system depleted of vitality cannot resist these unseen invaders, and easily succumbs to disease Of course, the total amount of oxygen in existence is not lessened, but is rendered inoperative.

The final question to be met is regarding conservation and restoration of the atmosphere How to conserve and how to restore? If natural law could prevail, a balanced atmosphere would be maintained, but it is a serious question indeed.

Closely allied to this are the problems of forest conservation and water storage, which we hope to take up in a future article

We respectfully submit that there are certain inalienable rights declared in the immortal document and secured under the Constitution as being common to all men. Among these are life, liberty, and the pursuit of happiness The right to live and to be free and happy

Necessary to life and enjoyment of it is health, and this cannot long be maintained under the adverse conditions of impure water and infected air Much has been done to secure a supply of pure water in our cities, but the air is just as much a common menace as ever. There are times when the only breathing places are the parks, the river front, and the shore; but how many of the poor never see them.

Air is the universal medium of life, and as such should be properly conserved, like any other universal privilege.

"All experience has shown that mankind will suffer, while evils are sufferable, rather than to alter or abolish the evils to which they have become accustomed."

Schroon Lake, N. Y WILLIAM MARSH.

The Harbors of the Pacific Coast

Terminal Facilities for the Panama Canal Trade

By Wm. Hosea Ballou Sc.D.

THE coast line of the Pacific coast of the United States is defined by the United States Coast and Geodetic Survey as 1,852 miles long from headland to headland, and 8,800 miles long with indentations. Originally its natural harbors may be said to have been confined to San Francisco, San Diego, those on Puget Sound and the Columbia River. As populations increased in California, Oregon and Washington, there was a corresponding growth in water-borne traffic, and Congress, from time to time, made appropriations for the improvement of rivers and harbors. Oregon has received the greatest sum, $24,500,000, California's appropriations have totaled $19,300,000, and Washington has been granted $10,175,000.

To the above should be added the immense outlay for railway terminal wharves, municipal wharf systems, and the expenditures by corporations and individuals, bringing the approximate total up to probably over $100,000,000.

State of Oregon.

PORTLAND HARBOR.—Portland is located on the Willamette River, 12 miles above its entrance into the Columbia River, which is 110 miles from the mouth of the latter, and at present is the head of deep water navigation. Light-draft boats may ascend the Willamette 150 miles. By using the State portage road between Celilo and Big Eddy, they may ascend the Columbia and Snake rivers during higher stages for an additional 537 miles, this last stretch being the greatest of American logging and rafting waterways. Logs from 20 to 90 miles inland are floated over tributaries to saw and shingle mills upon its banks. Rafts of logs and piling timbers, of 6,000,000 feet each, are towed over it during the season, and thence by ocean to California ports. The annual commerce amounts to eight million tons, valued at $75,000,000, of which a little over one half is sea-going.

Congress is asked to appropriate $1,844,000 additional for use this year in continuing the jetty work at the mouth of the Columbia River, bringing up the total expenditure to date of $11,488,000. More than as many millions will be required before this important entrance is under permanent control, and it is doubtful if its annual maintenance for dredging, etc., will ever be less than at present, about $105,000. Of the projected seven-mile jetty (the longest, by far, ever conceived), only about 19,000 feet were completed on the first of June, leaving some 18,000 to be constructed on the ocean end, in at least 40 feet of water. When it is finished, there will be still the north jetty to build—two thirds as long, and as costly. At the present rate of construction, it will require twelve years to complete the present south jetty and sixteen years to build the north jetty. Thus, a total of twenty-eight years must elapse before Portland can hope for a 40-foot channel such as admits shipping to New York harbor. Of its vast utility and necessity, however, there can be no doubt. The mouth of the Columbia River, which it is to control when completed, is 8,000 feet wide. The navigable channel within it swings like the nervous coils of a snake, moving its position 2,500 feet annually, first one way and then back again. The necessity of jetties on both sides, to compel the channel to remain in one place, is thus shown, so that by the use of dredges, it may be kept at the required depth.

COOS BAY.—Coos Bay is the second Oregon harbor in size, and it presents no especial natural difficulties to overcome. Vessels drawing 22 feet of water may now cross the bar at high tide, enabling the port of Marshfield to handle, last year, 300,000 tons of freight and 25,000 passengers, between it, San Francisco and Portland. The harbor is 180 miles south of the mouth of the Columbia River, and it is the principal ocean port of Oregon, being located in the center of or adjacent to the vastest forest region and the most fertile valleys.

The Coos jetty has a history far more inviting than that of any other on the Pacific Coast. When its construction was commenced in 1879, there were only 10 feet of water on the bar. The first project called for 1,760 feet of jetty, which was speedily built, at a cost of only $213,750. As the channel still continued movable, tortuous and unstable, Congress in 1890 ordered the north jetty continued to a length of 9,600 feet and the construction of a south jetty 4,200 feet long. The extension of the north jetty was completed in twelve years, at a cost of only $721,720, of which $196,721 was for maintenance. The channel deepened naturally and became stable, so that it was not necessary to construct the south jetty. Deducting maintenance, it will be seen that the actual cost of this jetty was only $77 per foot. After a lapse of ten years, the condition of the jetty is practically normal. Its eurockment has only slightly subsided. Its tramway and receiving wharf only have been destroyed, the result of the work of the teredo and consequent decay.

State of Washington.

TACOMA HARBOR.—Tacoma has one of the deepest harbors extant, ranging from 200 to 600 feet in depth. At the south end of the harbor are extensive tidal flats, bare at low water. The city water front is along the southwestern shore and the harbor lines have been established around the south end of the bay and along its western side. Several waterways extending into the flats have been projected, of which the most important, the City Waterway, has been completed at a cost of $162,480. Its depth varies from 25 feet to 15 feet at its south end. Tacoma's great harbor problem remains unsolved, and has languished for three years. This project called for the deepening to 28 feet of the Puyallup waterway for a width of 500 feet and a length of 3,650 feet. When one half of the work was completed, at a cost of $159,585, freshets brought down such large deposits in November, 1909, that the 1,811,589 cubic yards dredged were replaced by more than 1,000,000 cubic yards of debris. All work was then stopped and the channel has since refilled. A board of government engineers decided, after a survey, that the only solution of the problem was to divert the bed of the Puyallup River and have it empty elsewhere than into the waterway of that name. As such diversion is not comprehended in the scope of Government operations, it will never be done unless private, city or State interests do it. Meantime, Tacoma is going ahead with its wharf terminals on an extensive scale, leaving the Puyallup for later consideration.

GRAYS HARBOR.—Grays Harbor is the name of a top-shaped bay fourteen by seventeen miles in area, forming the mouth of the Chehalis River. On it are located the thriving sawmill cities of Aberdeen, Hoquiam, Cosmopolis and others, which contribute about 800,000 tons annually, mostly of lumber products, to commerce. Here the usual jetty problem was encountered at the outset, a convex bar having primevally formed two miles out at sea, across a channel about 100 feet deep, diminishing landwards to 30 feet. The two

entrances through the bar had 12 to 13 feet of water, periodically shifting. In 1896 Congress authorized a south jetty three and a half miles long to control the tidal currents existing between two sandy peninsulas, 12,500 feet distant from each other. In 1902, when the $1,000,000 authorized for the work had been expended and 13,784 feet of rubble-stone jetty completed, further work on it was abandoned. In 1907 Congress authorized a north jetty of 9,000 feet length, and, in 1910, its extension to 16,000 feet, to bring up its outer end opposite of the end of the south jetty. Local interests contributed the land for the trestle approach and operating plant. The jetty trestle is at present 12,784 feet long and the enrockment finished up to 9,376 feet, 8 feet wide at the crest, to the mid-tide level. Nature offers no such tremendous opposition and difficulties here as at the mouth of the Columbia River; but, for that matter, it is doubtful if the latter has any rival extant for battering and destructive powers.

SEATTLE's engineering problems do not call for much comment. The harbor works concern two fresh-water lakes, Union, within the city, and Washington, on its borders. A navigable connection with Puget Sound is proposed for the former, and the improvement of the Black and Duwamish rivers forming the connection of the latter. A channel has been dredged, 50 feet wide and 16 feet deep, between the Sound and the wharves at Ballard, in Salmon Bay, a distance of 2,000 feet, with a turning basin 175 to 500 feet wide. A cut has been excavated between Lake Union and Salmon Bay to control the water level of the former. From Ballard to the lock site the channel is 75 feet wide and 16 feet deep. In June, 1910, Congress authorized the construction of double locks to be located at the entrance to Salmon Bay, and an unbroken channel-way therefrom, through Salmon Bay and Lake Union to Lake Washington. The channel, or canal, is to lower Lake Washington to the level of Lake Union. The cost estimate was $3,555,000, of which Congress appropriated $2,500,000, for the locks and accessories only, Seattle agreeing to pay for the channel work and to secure the government from all damages for lowering Lake Washington or raising the level of Salmon Bay.

California.

SAN DIEGO.—San Diego's bar was originally cut by a natural channel 500 feet wide and 21 feet deep at mean low water. In 1875 Congress appropriated $80,000, with which a dike was thrown across the mouth of the San Diego River for the purpose of preventing its deposits from injuring the harbor. In 1890 Congress authorized the construction of a 7,500-foot jetty on Zuninga Shoal, at the harbor entrance, and the maintenance of a channel 24 feet deep. When this project was completed, the channel first deepened from 26 to 28 feet, then subsided to 24 feet. Continued dredging increased the maximum depth to 27 feet. The average tide here is 4.8 feet, as against 18 feet in the Pacific Northwest. In 1910, Congress authorized a channel 30 feet deep at the outer bar and 600 feet wide, so as to admit the Pacific squadron and enable the warships to coal at La Playa. This work will be completed by the time of the opening of the Panama Canal and the Panama-California Exposition at San Diego in 1915. The harbor has an area of twenty-two square miles, ceded to the city by the State. The city has appropriated $1,000,000 for a modern wharf system, with wharves 1,000 feet in length each and an additional sea wall 25,000 feet long. There are still 1,000 acres which can be utilized for commerce. A belt line railway is being built along the entire water front to facilitate the movement of freight.

LOS ANGELES.—Los Angeles harbor was created by the annexation of San Pedro's outer and Wilmington's inner harbors. Originally San Pedro Bay was an open roadstead, protected on the west by a bluff known as Point Fermin, but exposed from other directions. In 1897 Congress made available $2,900,000 to build a breakwater from Point Fermin 8,500 feet out into the Pacific Ocean. The fund was sufficient to extend the breakwater 9,250 feet from Deadman's Island, to terminate in 40 feet of water. This portion of the work consists of two straight arms, connected by a curve 1,800 feet long, having a radius of 1,910 feet. The westerly arm is 3,000 feet long, the easterly arm 4,450 feet long. Deadman's Island has been connected with the mainland by continuing the breakwater to 11,275 feet in length. The breakwater is 122 to 194 feet wide at the base, 38 feet wide at low water and 20 feet wide on top, 14 feet above low water. This breakwater can only be described as one of the greatest extant, creating, as it does, a magnificent roadstead out in the ocean. To construct it 2,563,777 long tons of rock were used, with rocks weighing three tons each and upward.

On invitation, Mr. Irving T. Bush, projector of the Bush Terminals of Brooklyn, has inspected Los Angeles' harbors with a view of suggesting how they can be made to anticipate the further increase of trade to result from the opening of the Panama Canal. He recommends the construction of a wharf three-quarters of a mile long. Such a wharf would be 2,900 feet longer than any now extant. The city has now twenty-two miles of improved water front.

SAN FRANCISCO.—San Francisco has the great advantage that it is a practically natural harbor. The Government has never had to concern itself in its behalf, except to remove rocks, which mostly protected above water, where they could always be seen and avoided. This natural harbor is forty miles long and from three to ten miles wide, with thirty-six square miles of anchorage area, ranging from 40 to 90 feet in depth. Its main entrance, Bonita Channel, has a permanent, unshifting depth of 48 feet, which never has and probably never will require a dredge. It has other channel entrances also, none of which have less than 30 feet of depth. The only impediments to navigation were the rocks mentioned, marked with buoys or lighthouses. Of these, Blossom, Arch and Shag rocks Nos. 1 and 2 have been removed to a depth of 30 feet, and also Noonday rock, thirty-three miles west of the entrance. Work was stopped on Rincon rock at a depth of 24 feet, when the city took the base over for a wharf and included it in the pier-head line. In 1910 Congress authorized a depth of 40 feet of water to replace Centissima rock, in Bonita Channel, and 35 feet of water in the place of two rocks near Mail Dock. In this work $515,928 have been spent and $250,000 more have been authorized. It is evident that San Francisco harbor must remain the only one on the Pacific Coast, for many years, that can admit the largest of the world's vessels.

OAKLAND.—Oakland commenced harbor building in 1874, and work has been done intermittently ever since. It is now a greater harbor than it has commerce for, and speculation is rife as to what benefits will accrue from its future enlargement. As it is, 64 per cent of its tonnage goes on ferry transfers across the bay, consisting of overland freight consigned to San Francisco. The harbor is essentially the San Antonio estuary, an arm of San Francisco Bay. The project of 1874 resulted in the construction of two high-tide training walls at the entrance, a tidal canal one and a half miles long and 400 feet wide, connecting with San Leandro Bay, a tidal basin with a channel to San Francisco Bay and three steel bridges across the tidal canal. Next, a number of channels were excavated into Oakland and the jetty was extended 500 feet. Since then canals and waterways have been deepened, the main channel to 30 feet and the widening processes have been continued up to 500 feet. To-day the tidal canal has been extended to four and three quarter miles in length, the channel around the tidal basin to two and three eighth miles and the channel in the tidal canal to two and one quarter miles. Congress has authorized further improvements to the extent of an additional $705,482, and has appropriated $150,000 of it to be spent this year.

The Pacific squadron assembled in San Diego harbor.

City Planning Congress at Duesseldorf, Germany, 1912.

DUESSELDORF, the most beautiful and modern city in western Germany, known as the "Park City" and the center of the industrial empire with its extraordinary commercial and political developments, probably without a rival throughout Europe, is at present holding an exhibition on city planning, city operation and city administration functions.

The exhibition will last from June 20th to October 31st, while the International Congress will be from the 23d to the 28th of September.

The first group of exhibitions consists of general ground plans, traffic systems, such as railways, local and express facilities, elevated, subway, suspension and street railways, aviation stations, city embellishment, bridges, docks, parks, lawns, forests and real estate politics.

Under city operation are grouped: Gas works, water works, electric central stations, sewage systems, street cleaning, refuse disposal, cemeteries and crematories.

Under the third group, administrative functions, are exhibited plans and models of hospitals, rescue homes, poor houses, lodging houses, orphan asylums, homes for widows and the aged and infirm, schools, churches, museums, art galleries, libraries, concert halls, etc.

It will be noticed from the foregoing items that this exhibition is planned with the well-known German thoroughness so that hardly any subject is omitted that is of importance in city planning, city operation and administration.

The addresses and papers will be read in the principal languages, German, English, French, etc.

Lieut. Scott Wins the Bomb Prize.

THE trials for the $5,000 Michelin prize for bomb dropping from an aeroplane at a height of 2,400 feet ended at Châlons on August 11th in an American victory, subject to confirmation by the French Aero Club. The winner was Lieut. Scott of the United States Army. Scott dropped the bombs three at a time. The first three fell outside the target, which was a rectangular space 170 by 40 feet. Subsequently Scott succeeded in dropping eight projectiles within the target. Readers of the SCIENTIFIC AMERICAN will doubtless recall a very interesting article that Lieut. Scott wrote for us about a year ago on his method of dropping bombs.

New York's Double Deck Car

LAST spring there was introduced in the streets of New York a peculiar low street car, which gained for itself the name of the "hobble-skirt" car or the "stepless" car for the reason that it was hung very low, and hence required no step between the street level and the floor of the car. This result was obtained by placing the driving motors at the end of the car and the car body between them. The entrance to the car was at the center.

When it was found that the low stepless car was a success, it was only logical for the next improvement to consist of an upper story placed over the low car. By an ingenious disposition of the various parts a double deck car has been evolved which is only seventeen inches higher than the ordinary car that runs up and down Broadway At each end of the car are the stairways that lead to the upper deck Here there are two long seats running the entire length of the car, and arranged back to back Thus the aisles of the upper deck are at the outside, whereas the aisle of the lower deck is in the center, where there is plenty of head room directly under the seats of the upper deck The seating capacity of the new car is 88 passengers, and there is standing room for about 80 more The seating capacity of the long open cars now in use is 60, and of the short ones, 50 While the long closed car will seat but 36 and the short ones but 28 The pay-as-you-enter-car has room for 41 to 47 seated, and the single deck stepless car has seats for 51

While the double deck car is a decided innovation in this country, it has long been in use in Europe. However, the design is decidedly different; in our car the stairways are placed at the side and are entirely enclosed, so that the passengers need experience no timidity about climbing from one deck to the other In mounting from the lower to the upper deck the passengers have to rise less than two feet more than they would in boarding an ordinary car. The upper deck of the car is roofed in, but the sides are open, except for a protective netting In the winter time this will be replaced with solid panels and windows. The car is now being tested to determine whether it can be unloaded and loaded rapidly enough, particularly from the upper deck As the only exit and entrance to the car is at the center there may be some difficulty from congestion at this point If it is found that the car may be readily unloaded and loaded there is no doubt that many cars will be ordered for use on the crowded streets of New York Thus, in economizing in the number of cars operated, there will be a material economy in operating expenses, and added to this there will be less congestion of the streets, and consequently a more rapid transit

Stairway to upper deck.

New York's new double-deck car. Only 17 inches higher than the ordinary car.

East African Cedar for Lead Pencils

THERE are about twenty lead pencil factories in and around Nuremberg, Germany, which consume approximately 100,000 tons of cedar wood annually. All of the lead pencil factories in Germany excepting one small concern at Regensburg are located at Nuremberg For 250 years the operators of these factories have been dependent on America for their supply of pencil cedar, which includes the northern red cedar (*Juniperus virginiana*) and the southern red cedar (*Juniperus barbadensis*). Suitable woods from other sources have been sought for a number of years, but none have ever been found that were so satisfactory, or that approached in quantity and quality the cedars of the eastern and southeastern United States It has recently been announced, however, that this dependence on the American product is almost at an end, since the extensive Schume forests of cedar (*Juniperus procera*) in German East Africa are being exploited. These forests are said to furnish a wood equal in quality to the average grades of the American cedars and sufficient in quantity to satisfy the needs of the German factories for a good many years to come.

The German government had an investigation made of these forests with a view to developing them and to render the timber supply available for use. It did not lose an opportunity to make known this large supply of cedar wood, and a concession has recently been granted to a company for the exploitation of this valuable timber. The company has constructed a cable-tram line at a cost of nearly $400,000, for the purpose of bringing the logs to the mills. It is the steepest cable-tram line in the world, and is said to be a masterpiece of engineering skill. The line is now being successfully operated, and the cedar logs are converted into lumber and transported by rail to the port of Tanga, in Usambara. From here it is shipped by the steamers of the East African Line to Hamburg—the principal distributing point.

Many government officers have tested the lead pencils made from this African cedar and have approved them; the Prussian ministries of finance and of the interior both have recommended that pencils made from East African cedar should be given preference. Practically all the leading German lead pencil factories are now using some African wood, and the pencils made from it are pronounced to be equal to those made from the American cedar.

Water-skating

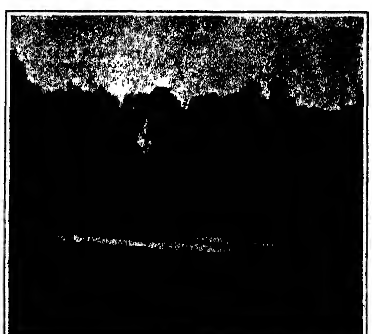
ATTEMPTS have often been made to design some means for enabling man to walk on the surface of water, and especially during the last few years a number of "water-skates" have been invented for the purpose However, all these designs showed the drawback of possessing a weight much too high, their dimensions were too great and transport too inconvenient and difficult over land to allow any pleasurable sport. In fact, the prospects of this fascinating water pastime were anything but promising.

However, on the Lake of Gross-Wusterwitz, in the Prussian Province of Saxony, water skaters moving with surprising agility have now made their appearance in great numbers. They use a novel type of non-rigid water skate constructed by the Deutsche Wasserlaufschuh-Werke, which may be said to eliminate all the drawbacks so far inherent in this mode of locomotion. These compressed air water-skates which embody the results of many years' studies and indefatigable experimenting, look very much like skis, have strikingly low weight and small dimensions, and accordingly allow the skater to glide on the water with an extreme ease. While in ordinary rowing one has to turn his back to the direction of motion, water skating has the additional advantage of allowing the face to be turned forward, so that the eye on account of the erect position can sweep freely over a wide expanse of water. A further advantage of the new water-skates, which on account of their low weight are readily transportable, is the possibility of folding them up into a small and extremely handy bundle, after allowing the compressed air to escape from the floats (consisting of pointed caoutchouc cylinders and rubber-coated sail-cloth covers). They are pumped up again and mounted for use with the same rapidity and ease.

At the underside of the water-skates are attached movable fins which by opening at every move, enable the skater to slide on with the utmost facility. Another possibility which affords additional variety is to use alternately or simultaneously with the work of the legs, a light paddle endowing the skater with a mobility attained by no water craft. Everywhere, even on the most frequented waters, will the skater be able swiftly to make his way through the crowd of ships and boats.

Water-skating in this new form seems to be anything but a dangerous sport. The feeling of absolute safety which is experienced by the users of water-skates is based in their very construction: The keel running underneath the water-skate (and tied up to the latter) insures a very sufficient stability, excluding any risk of tumbling. In fact, no fall or other accident has so far occurred on any one of the numerous trips made on water-skates nor in connection with the exercises of beginners even in rough water. However, provision has been made even for the remote possibility of an accident. In order not to be hindered in swimming the skater is, in fact, able with a single move to free his feet from the water-skates. The only back motion of the locking lever required in this connection is effected without difficulty and with an absolute safety in any position whatever. A safety device prevents any involuntary detachment.

Water-skates folded up for easy transport.



Gliding on the water may be assisted by a light paddle.

German and French Airship Rivalry

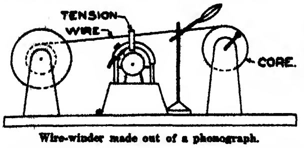
THE fact that one of the Berlin papers stated that Germany now had as many as 27 balloon sheds for airships, led the Paris daily *Le Matin* to resume the question of relative strength of these rival countries. Germany is laying great stress on the airship question and appears to prefer the airship as being best suited to the national character. The 27 airship hangars appear to lie mostly on the frontiers of the country, headed by the great Friedrichshafen hangar which takes two Zeppelins, then come Hamburg, Frankfort, Metz, and others. New hangars are planned at Wilhelmshafen for large marine airships gaging 25,000 cubic yards. It is difficult to say just how many military airships Germany possesses, for these are often transformed and their names changed, but there are probably not more than ten or a dozen fit for use. France has nearly the same number at present, and there will soon be three new airships finished. As to the hangars, there are 8 on the east frontier and many others in the Paris region or elsewhere which make about 20 in all. The position of the two countries is about equal as to the number of airships and hangars. Germany is spending large sums in this direction, and this is not the case in France, for the most of the attention is given to aeroplanes.

A Simple Wire-winding Apparatus

By Norman Barden

WHEN the amateur experimenter starts to building coils, the winding of the wire generally looks like a great task to him; and so it is when the wire to be wound is small and hundreds of feet are to be coiled. It so happened that the writer was interested in the making of a large ozone generator which had to be finished in a very short time. The secondary was to consist of 10,660 feet of No. 40 enameled wire. How to wind the wire in a short time without breaking it or having any laps in the winding was the problem.

The driving mechanism of an old model Edison phonograph was brought into use, and made to guide the wire and at the same time to keep it taut. This was done in the following manner: A tension was fastened to the bridge that carries the needle. The



Wire-winder made out of a phonograph.

machine was placed so that the tension was about three inches from the core, which had been put between centers as shown in the accompanying figure. The speed of the machine was then slowed down so that the core could be turned about seven times while the tension moved to the right a distance of one fiftieth of an inch, i. e., while the record cylinder made one revolution. In this way the wire was wound on the core, which was three inches in diameter, in one afternoon. A magnifying glass was used as shown in the figure to assist in watching for any kinks in the wire.

It was surprising to find how well the work could be accomplished when one person turned the core and another regulated the speed of the machine and watched for any trouble in the winding. With this arrangement, as soon as anything went wrong, the one turning the core would immediately stop, and the other person would drop a little paraffin on the wire on the core to prevent it from becoming loose. A part of the wire could then be unwound and the trouble fixed with no fear that the rest of the winding would be loosened. It was also found necessary to have the distance between the core and wire reel as short as possible. The shorter this distance the less danger there is of the wire's breaking. This last applies especially to the winding of the finer wires. Two other factors are to be taken into consideration. These are that the reel must turn very smoothly and easily, and that the winding must be done evenly and not by jerks.

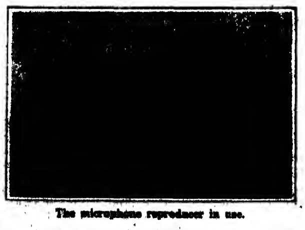
A Simple Microphone and Reproducer

By C. C. Kiplinger

HEREWITH illustrated is a simple microphone and also a rather unusual application of this interesting instrument. It comprises two short lengths of ⅜-inch electric light carbon. These are inserted in each end of a bit of ⅜-inch rubber tubing.

The ends of the carbon rods within the tube should be about ⅛ inch apart. This space is loosely filled with granular carbon free from dust, obtained by crushing arc-light carbons in a mortar. The granules should not be more than one thirty-second inch in diameter. The pressure on the particles may be varied by shifting one of the rods.

Copper wires are twisted tightly about each rod to



The microphone reproducer in use.

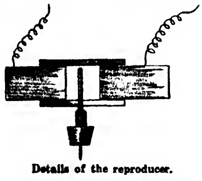
serve as connectors. If the carbons are copper-plated the wires should be soldered to the plating.

The instrument is connected in series with a telephone receiver and a battery of a half dozen cells. When the microphone is properly adjusted, a very small disturbance of the carbons will cause a corresponding movement of the carbon granules, and the resistance offered to the current will change. This causes a sound in the receiver. A cigar box provides a good sounding board for the apparatus.

With a slight modification, this device becomes a first-class reproducer for a gramaphone. The sound waves engraved on the record may produce electrical vibrations, which in turn, are reconverted by the telephone receiver into sound waves in air. A loud-speaking receiver will make these audible to a large audience.

A small slit is cut in the center of one side of the rubber connector. A short piece of three sixteenths inch brass tubing is flattened for a part of its length by hammering, and the flattened end passed through the slit so that it just clears the opposite side of the cavity. The flat surfaces of the tube should be parallel to the ends of the carbons. A small cork and needle are attached to the other end of the tube, as shown in the sketch.

The photograph shows the apparatus in working order. It is supported by a stand, a heavy wire, and a counterbalance of some sort. The connecting wires should be very flexible, so as to offer little resistance to the motion of the microphone. The sound waves inscribed on the record are transmitted to the carbon granules by the needle and brass tube. The receiver



Details of the reproducer.

may be at a distance from the reproducing microphone.

Very interesting results are obtained by changing the angle of the needle with reference to the disk, so that the record may be run in the opposite direction. The vibrations are reversed in order, as are the vocal inflections, producing in many instances extremely ludicrous effects.

Etching Glass With Hydrofluoric Acid

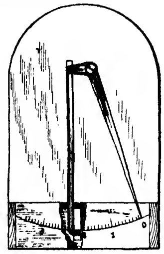
By Norman Barden

IT is sometimes desired to etch a small design in a piece of glass or a label on a bottle. To do this on small pieces of glass, not larger than twelve inches square, does not require a great deal of expensive material if done in the following manner: The glass piece to be etched is first covered with a thin layer of paraffin wax or beeswax. The design to be etched is drawn on a piece of glazed paper with a soft pencil. The drawing is now placed against the wax coating and is rubbed all over the back with some blunt instrument. On removing the drawing, the design will be clearly seen on the wax surface. The design is now cut in the wax, i. e., wherever the glass is to be etched, it is cut free from wax. Now, as to the etching, this can be done in two ways. The first method to be described is very convenient for etching small designs and graduation marks, as on thermometers and special graduates. A tuft of cotton is fastened to the end of a piece of copper wire. With this, hydrofluoric acid is swabbed over the design until it is etched the proper depth. The operation must be carried out in a well-ventilated place or in a slight draft. The fumes of the acid should never be breathed, and the acid itself produces severe burns if it touches the skin. Commercial hydrofluoric acid is obtained in paraffin-lined bottles, and must be kept in these containers or in gutta-percha flasks. For the larger pieces of glass to be etched, it will be found best to do them in the following manner: Finely crushed calcium fluoride or fluorspar is sprinkled over the bottom of a shallow lead tray. A lead tray can be easily made from sheet lead by bending the edges up to form the tray sides. Over the fluorspar is poured concentrated sulphuric acid. The spar does not have to be entirely covered by the acid. After the design has been prepared the glass plate is laid, face down, on the lead tray. It is best to have both sides of the plate covered with the wax when the etching is done, in the following manner: To etch the glass, apply gentle heat to the pan. This may be done with a spirit lamp or the Bunsen flame. This operation should be carried out in the open or under a hood in connection with a chimney or an exhaust fan. The etching in this last case is done by the hydrofluoric acid vapors that arise from the heated fluorspar and sulphuric acid. The one great caution in etching glass is not to inhale any of the acid fumes and never let the least bit of the acid come in contact with the skin.

A Home-made Hygrometer

By C. S. Meeker

THE accompanying engraving illustrates a home-made hygrometer constructed by the writer more than thirty years ago. The instrument worked well for twenty-five years when it was accidentally broken. The instrument consists of a baseboard upon which is mounted a pointer cut from sheet metal. The pointer is ten inches long and is provided with a lateral arm



Hygrometer with wooden expansion member.

at the pivot end one inch in length. The end of the pointer passes over a scale at the bottom of the baseboard, graduated in tenths of inches. The short arm of the pointer is fastened to a piece of clear soft pine, ½ inch square, cut with the grain running crosswise. The lower end of this pine stick is fastened to a stud which passes through a slot in the baseboard and is adjustable therein to bring the pointer to the zero mark on the scale. The pine stick was dried in a kiln and after being taken out was allowed to cool, when it was set at such an adjustment as to bring the pointer to zero on the scale. An expansion of one 0.01 inch in the wood would cause the pointer to move 0.1 inch. The instrument was placed in a shed where neither rain nor sun could reach it. On several occasions the pointer stood at zero and at one time it reached as high as two and two-tenth inches, showing, therefore, an actual variation in the length of the stick of over a fifth of an inch between the dry and damp weather. The device was not made as a hygrometer, but was constructed primarily with a view to ascertaining the expansion and contraction of timber.

Improved System of Filtering

By Clarke E. Davis

THE large inverted bottle shown in the cut is fitted with a two-holed rubber stopper, through one hole of which passes a short glass tube extending upward just through the cork and downward to the funnel. In the other hole is inserted a glass tube, which reaches to the bottom of the bottle and terminates at the other end in a piece of rubber tubing fitted with a clamp.

This clamp serves to regulate the inflow of air,

Filter with regulated air flow.

which controls the outflow of the liquid. The funnel is supplied with an ordinary plaited filter.

This system of filtering is advantageous because it may be started and it will take care of itself to completion, thus enabling one to filter the various precipitated reagents, etc., while conducting a session or enjoying a meal.

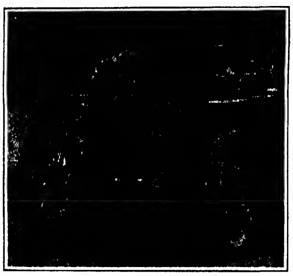
Self-starter Device for Automobile Engines

By Theodore M R. von Kéler

THE difficulty of starting a powerful automobile engine on a cold day by means of an ordinary hand crank has been brought home with considerable force to those owners or drivers of high-powered cars who operated their cars before the arrival of the various systems of self-starters which now are on the market. And even now, despite the presence of several systems of starting devices, the difficulty is by no means fully solved, for even the most perfect ignition, piston pressure or electric device made, will balk occasionally Any invention, therefore, which promises to do away with at least some of the troublesome difficulties encountered, deserves careful investigation.

Differing radically from every other motor starting device so far brought on the market, the Air Starter contains features which never before have been brought to a practical test, but which appear so logically correct that one cannot refuse them due consideration. The device, which is manufactured by a Detroit company, recently was exhibited in New York city streets, attached to a sixty horse-power, four-cylinder touring car. In several hundred demonstrations the apparatus worked without a hitch.



The position of the air starter supported on the springs in front.

The device consists of a small two-cylinder opposed air compressor, a compressed air tank and the air crank. This last named part of the invention is the most radical departure from accepted designs of compressed air starters. Instead of forcing compressed air or exhaust gas into the tops of the cylinders themselves, and forcing the pistons down by this means, the air crank simply replaces the human arm on the crank handle and turns the crank by means of a mechanical arm. How this is accomplished is clearly visible in the accompanying diagram

The air crank consists of a semi-circular cylinder in which a piston is free to move in an arc of about 160 degrees. The piston is firmly attached to the crankshaft by means of a cranking arm fitted with a rachet device When compressed air from the tank is admitted into the cylinder—which is accomplished by simply pressing a button on the foot board —the piston is pushed around with great speed and power until the cranking arm hits the bumper, which movement is equal to turning the engine over two or three compressions As soon as the bumper is touched the rachet device is disengaged and the long helical spring returns the cranking arm and piston to their original positions. In case of a back fire before the arm has reached the end of its turn, the ratchet is also disengaged by contact with a tripping pin acting as an automatic release, and the crank arm returns to its normal position.

In addition to cranking the motor the compressed air tank is arranged so as to accomplish other work around the car. A hose valve on the dash, and a length of flexible hose with a tire gage for filling the tires, dusting the car, etc., are provided. An air signal can be connected, powerful emergency air brakes attached, constant pressure supplied for the gasoline tank, etc. By simply pressing a foot button when the car is running, the driver can connect the compressor at will It is claimed that operating the compressor for about five minutes two or three times a week is sufficient to maintain a pressure of 250 pounds in the storage tank. An air gage on the dash indicates the pressure.

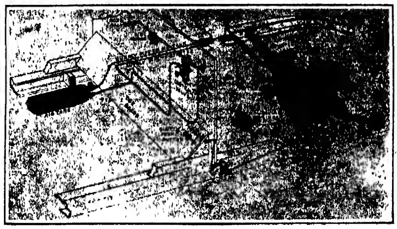


Diagram of installation of air starter device, showing connections between air crank at the right and air tank push button.

A Tractor Steering Device

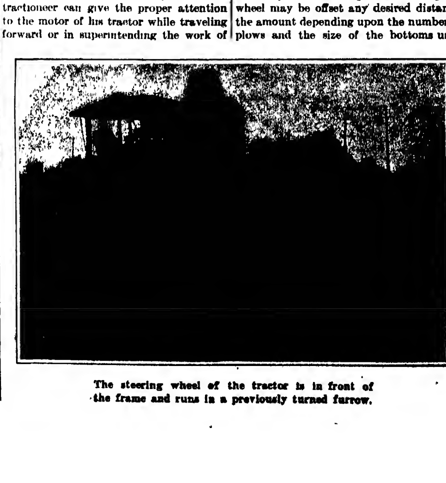
THE growing use of tractors and the scarcity of reliable trained help has led to the invention of a substantial device that automatically guides a tractor in plowing or in breaking and does it even better than the average man can do it. At the same time it makes it possible for one man to operate both engine and plows. The tractioneer can give the proper attention to the motor of his tractor while traveling forward or in superintending the work of his plows, as the occasion requires, and the tractor equipped with such a guide turns straight furrows of equal width.

The guide is made of high carbon channel steel securely braced and bolted together The principal factors are two ¼-inch × 5⅛-inch × 4-inch channel steel beams, 13 and 14 feet long, respectively, bolted to each other by brace rods of the same size material, so as to form a triangular frame

At the front end of this triangular frame is a single wheel and a long steel shoe The wheel runs in the previously turned furrow —hugging the "landside"—and by the leverage it exerts on the axle, keeps the front wheels in line. The distance from the tractor to the furrow is easily regulated by a simple adjustment of two arms on the angular frame

The shoe at the front end of the frame affords protection against any accident to the guide should the wheel drop in a hole or strike an obstruction. It also keeps the device free from weeds and other trash. If the guide should strike a hummock, there is no chance of it doubling up, because the shoe will assume the burden and hold it until the wheel once more has smooth footing. The front wheels are held firm, that is, kept from see-sawing.

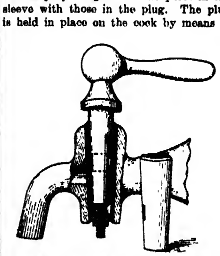
This device does not interfere with the backing of the engine, and in turning, it describes a circle only four feet greater in radius than the front wheels. In attaching the guide to the engine, the steering chains are detached from the front axle and connected up with the cables on the steering device, which, in turn, are held in alignment by two cable guides. The guide wheel may be offset any desired distance, the amount depending upon the number of plows and the size of the bottoms used. When the end of the field is reached the turning is done in the usual way by the steering wheel of the tractor.



The steering wheel of the tractor is in front of the frame and runs in a previously turned furrow.

Plug Cock With Removable Sleeve

A PLUG cock or faucet is much more desirable than a compression cock or screw faucet because it is cheaper to produce and is quick acting; for a quarter turn or less of the lever of the plug cock will wholly shut off the flow, or open it to full flow, whereas with a compression cock, several turns are necessary. However, the objection to a plug cock is that they are not durable and are apt to leak. Furthermore, the repair of a plug cock is rather expensive. Trouble usually manifests itself in wear of the edges of the ports and the only way of repairing the damage is to replace the worn off plug with a new one. In order to reduce this item of expense and provide a ready means of repairing a worn off plug cock an inventor has recently designed a cock having a removable sleeve on the plug. When the ports through this sleeve become badly worn it is a simple matter to remove the plug from the cock and replace the worn sleeve with a new one. The details of the invention are shown in the accompanying cut. A key on the body of the plug fits a keyway in the sleeve and insures proper register of the ports in the sleeve with those in the plug. The plug is held in place on the cock by means of a nut bearing against a split-ring washer, not shown in our engraving.



Plug cock with removable sleeve.

An Improved Ship Construction

ON June 11th, 1912, there was issued a patent, No. 1,029,546, to Joseph William Isherwood of Middlesbrough, England, which, it is claimed, will revolutionize the building of vessels. The invention relates largely to the framework of the vessel and seeks to so distribute the metal of the framework of a ship as to cause the skin and deck plating of the ship to form an essential part of the bracing structure, making this said plating do work or resist strains which ordinarily would be resisted by the framework only.

From this, it is asserted that considering ships of equal strength and seaworthiness, of say three hundred feet long, it is found they can be built with about five hundred tons less metal than under the ordinary construction, effecting a saving in cost of say thirty thousand dollars. The particular method of construction consists in making the transverse frames and beams a plurality of times stronger and spacing them a plurality of times farther apart than has heretofore been customary in the same type of vessel, and also in making said frames and beams of a less total weight in metal than has heretofore been customary. The particular feature upon which patentability rests seems to consist in the discovery that the complex twisting, racking and breaking strains to which a ship is subjected in a seaway, and which defy calcula-

tion, will be efficiently resisted by this particular disposition and saving of metal.

Although it has only been, say, about three years or a little over since the first vessel went to sea under this system, yet to-day it is claimed there have been built or are now building over two hundred large vessels using the method, aggregating in cost upward of sixty millions of dollars. Also that a very large number of vessels has been built or are now being built in the United States under this system and that only recently the navy has had completed two colliers constructed according to this invention.

The Trade-mark as a Business Asset

By W. E. Woodward

[*THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer; that it is a symbol of good will, a tangible asset with a determinable money value; that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.*

The following is the seventh of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

The Elements of a Good Trade Mark—VII.

(*Continued from page 143, August 17th, 1912.*)

The reader who has perused the preceding articles devoted to a discussion of what a trade-mark cannot be, begins to wonder, perhaps, what part of the language is left unrestricted. It is true that the number of restrictions imposed by the law and the courts is considerable, but the language is virtually inexhaustible, with its infinite possible combination of letters and words. And to these possibilities of construction must be added the limitless varieties of designs and symbols which are registrable and valid under the law.

A trade-mark may be:

A coined word, like *Calox, Coca-Cola, Omo, Jap-a-Lac, Crisco, Pebeco, Celluloid, Pleao* (a trade-mark for suspenders; also for a toilet preparation), *Sapolio, Cravenette, Jell-O, Kodak, Uneeda, Pro-phy-lac-tic, Crex*, and *Quixo*; a symbol (like the Baker chocolate girl), the Prudential Insurance Company's trade-mark (which consists of a picture of the Rock of Gibraltar), the Merrimack duckling, the spear of Spearmint chewing gum, the Puritan painter (used on Bay State brick and cement coating), the Ford automobile mark (consisting of a winged pyramid), or the representation of a mask or domino (used on packages of Crystal Domino sugar), or the painter boy of the National Lead Company; a combination of word or words and a symbol (like Thomas A. Edison's portrait and signature, used in connection with phonograph), a picture of a black cat and the words "Black Cat" used as a hosiery trade-mark), the trade-mark of the Vacuum Oil Company (consisting of a picture of a gargoyle, in connection with the word "Gargoyle"), or a representation of a swan, accompanied by the word "Swan" (used on fountain pens); a portrait (like Mennen's Talcum Powder mark, which is a picture of Gerhard Mennen), or the portrait of Robert Burns (used on cigars); a word, or words used in a fanciful, non-descriptive sense (like "Cat's Paw," a trade-mark for rubber heels), "Bachelor's Friend" (a suggestive trade-mark for hosiery), the word "Ribbon" (a mark for a tooth-paste), "Republic" (used on automobile tires), "Velvet" (a trade-mark for smoking tobacco), "Onyx" (the trade-mark of a well-known brand of hosiery), "Ivory" (which stands for a famous brand of soap), "Diamond" (a name for tires), "Arrow" (used on collars), "Blue Jay" (a trade-mark for a corn plaster), "Big Ben" (used on alarm clocks), "Lifebuoy" (the name of a soap), or "Occident" (the name of a flour); an historical or a mythological character like Juno, King William, Stonewall Jackson, Cupid, Venus (a lead-pencil trade-mark), Samson (applied suggestively to a brand of rope), or Apollo (the name of a piano-player); initials or arbitrary numbers (like the "G. E." trade-mark of the General Electric Company), the number "4711" (applied to perfumery and toilet articles), "61" (a floor varnish), "O. K." (the name of a clip to hold papers together), "B. V. D." (the trade-mark of a well-known line of underwear), or the big "H" inclosed in a diamond-shaped design (used as a trade-mark on Heisey's glassware); the business name, of person, firm or corporation when written, printed, impressed, or woven in a distinctive manner, or in association with a portrait, or in an autographic form, as, for example, the name "Gillette," inclosed in a diamond and crossed by an arrow.

Marks that may be technically defective are registrable under the ten years' clause if they have been in exclusive use by the applicant for ten years preceding 1905. The word "Faultless," registered by E. Rosenfeld & Co., of Baltimore, as a trade-mark for garments, belongs to this class. "Faultless" is, of course, descriptive, but it is nevertheless registrable under the ten years' clause. Another mark of the same kind consists of the word "Coward"—a trade-mark for shoes. Coward is the proprietor, and under the act of 1905 his name has no eligibility as a trade-mark unless it is written or printed in a distinctive manner. But his name has been used as a trade-mark since 1868, and, consequently, falls within the provisions of the ten years' clause.

It is easy enough to devise a trade-mark that will comply with the letter and the spirit of the law. But a trade-mark should be something more than merely registrable and protectable. Think of the immense advertising and selling effort that must be brought to bear to overcome the inertia of a meaningless or unsuitable trade-mark.

A proposed trade-mark should not be adopted until every one of the following questions can be answered affirmatively in regard to it:

1. Is it easy to speak?
2. Is it easy to remember?
3. Is it easy to spell?
4. Is it simple in design?
5. Is it attractive in sound and appearance?
6. Is it suggestive of the good qualities of the merchandise?
7. Is it different from other trade-marks of the same class?
8. Can it be affixed to the goods with which it is to be used?
9. Is it registrable and protectable?

Competent trade-mark experts never submit a proposed trade-mark until it has passed this rigorous examination successfully. Few trade-marks in commercial use can stand these tests because most marks have been designed without any clear perspective of the part they were to play in business.

As a matter of interest and instruction, let us take several well-known trade-marks, at random, and put them through the list of test questions.

Opening a current magazine, the first trade-mark we see is "Postum," the name of a substitute for coffee. Postum is easy to say and remember and spell. It is simple, but not particularly attractive in sound. It has no suggestiveness, except the artificial suggestiveness of familiarity. It is distinctive, registrable and is virtually infringement-proof. If the figure 100 should be set down as denoting a perfect trade-mark, then Postum should be graded at about 80. It wholly lacks suggestiveness, and it is neither attractive nor displeasing.

The next mark that attracts our attention in this magazine is "Siwelclo," a coined word, applied to a flushing device used in connection with bathroom toilets. Siwelclo is not easy to pronounce; it is not euphonious; it is not easy to remember or to spell. It is the reverse of attractive in sound, and it carries no suggestiveness. It is registrable and protectable.

The next trade-mark is "O. K.," applied to paper fasteners. This mark possesses every good feature. It is suggestive in the sense that "O. K." means, in ordinary speech, "all right," "satisfactory," "good." These fasteners are used in offices. The symbol "O. K." has a distinct meaning in commercial language. We are of the opinion that "O. K." used as a trade-mark for office supplies, should be graded 100.

"Cat's Paw," a trade-mark for rubber heels, is the next. It is an example of a word that is suggestive in the wrong way. "Cat's Paw" suggests the soft quiet tread of a cat—and of rubber heels. At first glance it would seem that "Cat's Paw" is an ideal name. But those who sell rubber heels say that the noiseless tread (or "sneaky walk" as one shoemaker stated it) is the greatest of all drawbacks to the sale of rubber heels. In short, the name is suggestive, but suggests a defect.

Next we come to "Ralloc," which is the trade-mark of a collar retainer. The word is obviously the word "Collar" spelled backward. It is not euphonious or attractive, or distinctive in any way. This mark is an example of a large class of trade-marks which bear upon them the evidences of only one purpose—and that is, to produce something which will not be rejected by the Patent Office.

"Crex" is an excellent trade-mark. It is an adaptation of the word "Carex," the botanical name of a sedge-like grass which may be woven into a fabric. Dropping the "a" we have "Crex." This name sticks in the memory; it is easy to spell, easy to say, and is quite distinctive. It lacks inherent suggestiveness, but it is the kind of word that may be readily popularized by advertising.

There is a toilet preparation widely advertised and sold under the name "Sempre Giovine," meaning "always young." This trade-mark must be a tremendous drawback to the success of the article with which it is associated. It cannot be pronounced properly except by those who have taken lessons; and it is difficult to remember. To an English-speaking person it conveys no suggestion. Foreign words should be avoided in devising trade-marks. People do not like to ask for things by names which they cannot pronounce.

The trade-mark affixed to the linens sold by McCutcheon, of New York, a store famous for the quality of its fabrics, consists of the picture of an old-fashioned spinning wheel, without wording. This is a very good trade-mark. It brings up a mental picture of the slowly-wrought hand-woven linens of our grandmothers' time, fabrics that looked good and wore well.

There are trade-marks so admirably adapted to their purpose that they seem to be the work of a genius. "Uneeda"—applied to crackers in a sealed package, is such a trade-mark. "Rainbow," a trade-mark for dyes is another happy inspiration. This name makes one think of the fine colors and delicate tones of a rainbow. It stimulates the idea that these dyes emulate a rainbow in beauty. "Skidoo"—a trade-mark used in connection with a small gasoline engine for launches—is another trade-mark that touches the top notch of merit. It suggests agility and lightness, and the ability to get in motion and scurry away.

(*To be continued.*)

Notes for Inventors

Shortening a Moving Picture Film.—Patent No. 1,032,172 to Ernesto Zollinger of Turin, Italy, discloses an improvement in producing and projecting moving pictures wherein he deforms the picture on the film by reducing one of its dimensions to a fraction thereof and then projects the deformed picture through a deformer to reconstruct the projection to its normal proportions. Thus he can shorten up the picture in producing it and when he comes to project the picture on the screen he can lengthen it by suitable means to bring it back into condition to properly represent the subject he seeks to produce.

A Man Who Throws Ball to Himself.—Fred H. Wood of Elgin, N. D., has patented No. 1,030,558, a ball returning device which includes a curved tubular casing into the lower end of which a ball may be thrown, the upper end of the casing being returned slightly and a deflector plate being adjustably disposed with reference to the upper discharge end of the chute so its position can be varied in order to regulate the angle at which the ball is projected from the discharge opening.

A Domestic Dough Kneader.—In our issue of July 13th we published a brief note to the effect that somebody ought to invent a domestic dough kneader. A subscriber informs us that such an apparatus is already on the market. It consists of a twenty-quart pail having a bearing for a crank mounted on its top and a depending mixer attached to the crank. This mixer is a pointed finger, curved about one half of an arch, its lower end being about one half an inch from the bottom of the pail. We are assured that such kneaders can be obtained in almost any hardware dealer's store.

A Home-made Fly Catcher.—In one of our markets the small wholesalers have provided home-made fly catchers on a large scale. On a base board is mounted a length of fly screen-wire secured at its ends and sides to the board and elevated at the middle so the bait, usually fish heads, can be placed below the elevated portion. At one end the base wire inclines upwardly forming an entrance platform and a cover wire overlies the base one, and forms with it a chamber in which the trapped flies accumulate. The trap is simple and yet effective and attracts considerable attention in view of the campaign against the fly nuisance.

Brick Laying by Machine.—In a recent patent there is provided a machine for building up walls from superposed courses of brick with the interposition of mortar or cement between the bricks of the courses as well as between the courses. The machine has a rotatable brick carrier upon which the bricks are automatically gripped during a portion of the revolution of the carrier and from which the bricks are released when the carrier has conveyed the brick to its final position. The patent, No. 1,033,954, has been granted to Max George Shindler and Linus Paul Shindler of Hamburg, Germany.

Reducing the Noise on Street Curves.—Recently in Washington city a lady secured a judgment against a street railroad company for damage to her dress by the heavy oil used to lubricate a track curve to reduce wear and eliminate the scream-like noise when a car rounded the curve. As a result, the company stopped oiling the curve and the noise at times is almost intolerable. Some means, possibly mechanical, may be devised to overcome the friction between the wheel flange and curved rail and thus dispose of the noise nuisance and also avoid the excessive wear of wheel and rail.

A Mechanical Bow for Stringed Instruments.—A patent, No. 1,034,293, has been granted to Joseph von Pechl of Vienna, Austria, for a mechanical bowing device in which there is a movable carrier provided with rollers and a bow band traverses the the rollers and forms, with the carrier, a complete bow. Pedals are arranged for shifting the bow transversely of the strings as well as for controlling the pressure of the bow band upon the strings in order to secure the desired results.

RECENTLY PATENTED INVENTIONS

These columns are open to all patentees. The notices are inserted by special arrangement with the inventors Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN

Pertaining to Apparel.

SHIRT -H SALTZMAN, 435 Jerome Ave, Brooklyn, N Y This improvement is in shirts provided with a plurality of lapels attached to the body adjacent the waist line thereof, to enable the shirt to be attached to the trousers and support them, thus allowing the wearer to dispense with suspenders The shirt is made strong throughout so that it will not be readily torn in use

Pertaining to Aviation.

FLYING MACHINE —R L BERNARD, Mountain View Cal This invention combines the main features of an aeroplane and a helicopter whereby certain advantages are attained in respect to starting and alighting, direction of flight, poising, maintenance of equilibrium regulation of speed, and general safety It is applicable to both monoplanes and biplanes

Electrical Devices.

ELECTRIC MOTOR E S. WETMORE, College Springs, Iowa The motor devised by this inventor has a ratchet wheel and an electromagnet and armature, pawls on the armature engage the ratchet teeth which are part of the circuit, and the relative movements of the parts make and break the circuit

ELECTROLYTIC CELL —A TOMMASINI, 3418 Independence Ave Kansas City, Mo The object in view is to provide an arrangement of means for passing a current of electricity through a solution containing water in such a manner that the hydrogen bubbles created thereby will be directed to one point of discharge, and the oxygen bubbles will be directed to another point of discharge.

Of Interest to Farmers.

PORTABLE ORCHARD HEATER —M B FITTS, Minneapolis, Kan This invention generates steam and discharges the same along with hot air and heated products of combustion for any desired purpose, but it is particularly adapted for use as an orchard heater, that is to say, for preventing injury by low temperature to fruit and other trees, also to plants and vegetables

BINDER TRUCK —H J DRAGER, R. R, No 1, Orlando, Okla This truck is for attachment to a grain binder, for drawing the latter over the field or for transporting the binder from place to place. For this purpose the truck frame is arranged at its rear end for pivotal connection with the binder, and on the front end is pivoted a tongue and an evener, and in the rear of the front end is arranged a swiveled supporting wheel to support the truck frame

Of General Interest.

ILLUMINATED ENAMELED METAL BARBER'S POLE —F DE PALMA, 236 Central Ave, Brooklyn, N Y This invention provides a structure the parts whereof are readily combined and quickly renewed; provides for securing the structure in position, provides means for preventing wear or waste incident to employment showing on the structure to impair the appearance thereof, and provides access to the interior of the pole When the post or sign is employed as shown in the illustration as a sidewalk sign the base above the sidewalk is raised and the same is lifted away from the corroding influence of water held on the sidewalk

ILLUMINATED ENAMELED METAL BARBER'S POLE

WOVEN FABRIC - WILLIAM G TRAITVETTES, Paterson, N J The invention provides a fabric having interwoven bias or diagonal threads to reinforce the fabric and render it strong, durable and capable of withstanding strains in any direction For this result the fabric is formed of interwoven ground warp threads bias warp threads and weft threads, of which the bias warp threads extend diagonally across the fabric from one selvage to the other.

APPARATUS FOR DISTILLATION.—P. J. MATTINGLY, T. J. HINES, and J. J. BRENNAN, care of J Seligman, Kenyon Bldg., Louisville, Ky This invention has for an object to procure a more refined distillate by removing from the product all congeners which are of low grade and which are volatile only at higher temperatures, thereby producing a more refined product.

PROCESS OR METHOD OF MANUFACTURING ENVELOPS OR BAGS.—A. WASMUS, 16 Wolchonka, Moscow, Russia. The subject matter of this invention is a process or method of manufacturing envelops or bags, particularly those having threads for opening them, which consists in the flaps being folded around a tightly tensioned thread serving as an abutment.

NON-REFILLABLE BOTTLE. E. J. HEIL, Carteret, N J The purpose here is to provide a non-refillable bottle with a member having an annular groove in which is disposed a resilient catch, the terminals of which extend into a recess in the neck of the bottle, to prevent the removal of the member after the member has been pushed into position.

WAGON GATE.—W HOPPER, Jefferson, Iowa. This invention refers particularly to gates for wagons which are used for hauling and storing grain Their bodies often have to be hoisted to deliver the load of grain carried thereby into bins and other compartments formed inside structures where grain is stored; and this invention comprises means for readily operating these wagon gates after the same have been lifted to permit grain to be discharged therefrom

Hardware and Tools.

SWIVEL JOINT —F. G. HAYES, 31 Ohio St, Sharon, Pa This joint is for use on devices where it is desired to revolve the device or a portion thereof, the said revolving movement being substantially controlled by the operator To obtain this, use is made of a body provided with a cap, and means on the body for revolving the same

SUSPENDING DEVICE FOR STORM WINDOWS AND LIKE STRUCTURES.—J. M. IIJERMSTAD, Red Wing, Minn This invention is intended more particularly for use in connection with storm windows, screens, etc., such as are removably swung by their upper ends so as to admit of being fastened in vertical position in a window or door opening, or swung on their supporting means to a position inclining to the opening.

Heating and Lighting.

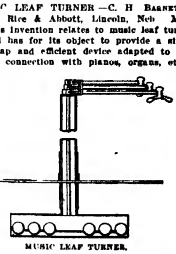
DRIER —J. C. COGBURN, Marietta, Ga Mr. Cogburn's invention relates in general to a drier, and more particularly to that class of driers known as "hot air driers" The invention supplies a continuous current of hot air directly to separate drying compartments; withdraws saturated air from each compartment by means of a fan attachment, and regulates the admission of unsaturated air to the device

INCINERATOR FOR GARBAGE, ETC.—L. MATTHEWS, Paris, Tenn A series of compartments is adopted to receive pans holding material to be incinerated and with a series of grates corresponding with the compartments, one or all of which may be used at a time, the arrangements being such that fumes from the material being incinerated and the products of combustion from the fire-boxes are directed into a common exit flue

Machines and Mechanical Devices.

AUTOMATIC SHUT OFF CONDUIT —ISABELLA GILLEN, Rockaway Beach, New York, N Y This invention is an automatic shut-off for conduits, such as gas and water pipes, and is designed to operate a valve to close said pipe in case of fire, to prevent the contents of the pipe or conduit from escaping in case the pipes inside of the house or building communicating with the conduit should be broken or damaged.

MUSIC LEAF TURNER —C. H BARNETT, care of Rice & Abbott, Lincoln, Neb Mr. Barnett's invention relates to music leaf turners, and has for its object to provide a simple, cheap and efficient device adapted to be used in connection with pianos, organs, etc., for readily and quickly turning either forward or backward the leaves of sheet music or music books The entire device can be packed in a small space, indeed, the shelf may be entirely removed from the standard and the entire device put in a receptacle large enough simply to receive the base. The illustration pictures a front elevation of the device.



MUSIC LEAF TURNER.

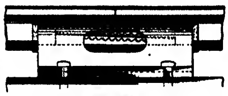
PADDLE MECHANISM FOR VESSELS.—W. H. WITTE, Charles St. Ave., Homewood, Baltimore, Md. This invention provides mechanism for propulsion in shallow streams; provides means for reversing, arresting and suspending the operation of the paddles of the mechanism to operate at various depths or to suspend the propulsive operation without stopping the machinery; and provides a means for preventing the inflow of water through the joints of the paddle box.

WATER LIFT.—B. F. STRANGE, 1.—R. F. D., Victor, Mont. This invention is especially adapted for elevating water to the uplands for irrigation and other useful purposes. It provides a mechanism for lifting water continuously from a lower level to a higher one especially adapted for use in irrigation. The flume or ditch may be of any desired construction, the size and length depending on the country in which the outfit is used. The operation of the car and the pusher may be continued for any desired length of time, and as many cars may be employed as can be taken care of, the operation affording a continuous supply of water to the upper level. The engraving shows a sectional side view of the water source and means of elevation to distribution points.

WATER LIFT FOR IRRIGATING.

Railways and Their Accessories.

RAIL JOINT.—C. W. YEBBURY, 528 W. William St., Springfield, Ill. This invention relates generally to a rail and more particularly to a fish plate, adapted for use on steam, electric and elevated roads, or in mines or quarries, or any place where a construction is required to hold rails together for tractive service. The invention provides means for holding adjacent ends of meeting rails, arranged so that bolts or equivalent devices are not necessary. Further, a structure is provided which by reason of the arrangement of the parts is well adapted to hold the meeting ends of adjacent rails in position and insulated from the roadbed, thereby facilitating operation and maintenance of signal systems, which make use of the rails as parts of the circuit. A side view of the invention in operative position is herewith shown.



RAIL JOINT.

PNEUMATIC POWER PAINTING MACHINE.—F. DYKES and D. E. WALLS, Milliken, N. Y This hand-guided, power-rotated brush delivers and spreads paint upon a prepared surface; it controls the supply of paint; and spreads the paint in the delivery thereof to the surface to avoid lumping or streaking of the finished product. Controlling devices for the brush manually control the quantity of paint and the spread thereof.

CONVERTER VALVE.—P. E. GANNON, P. O. Box 94, Jerome, Ariz. This invention relates to valves utilized in connection with the wind boxes of converters, particularly copper converters, which are adapted to permit of the insertion of a rod therethrough, such rod being extended through the tuyere for the purpose of preventing the latter from clogging while impurities are being blown out of the copper

ADDING MACHINE.—J. W. WITSELL, 37-39 Haynes St., Charleston, S. C In this instance the invention is an improvement in adding machines, and has for its object the provision of a simple and easily operated device of the character specified, of a size which permits it to be placed conveniently on the desk near the user, and which has few parts to get out of order.

WELL PACKING.—E. G. BOUTTE, St. Martinville, La., care of Bennett Oil Co., Opelousas, La. This invention is an improvement in packings, and has for its object the provision of a device especially adapted for deep wells, designed to be operated by a cable or the like, and adapted also to act as a seal for the well when required.

ATTACHMENT FOR SEWING MACHINES.—H. L. LAMB, 1409 Tremont St., Nashville, Tenn. The object here is to provide means adapted to be attached to the stabbing device of harness sewing machines, for channeling the leather in advance of the stitching mechanism, to provide a channel or groove for receiving and hiding the thread or stitch.

Pertaining to Vehicles.

PNEUMATIC WHEEL.—A. H. SMITH, Topton, Pa. The parts of this device being assembled and the annular cushion being inflated, the weight of the axle and parts carried thereby rests directly upon the inner surface of the pneumatic cushion and is thence transferred to the tire. The edge of the disk carried by the axle being loose relatively to the plates, is free to move relative to them and to the tire, the limit of movement being the degree of compression which the annular cushion can undergo. The cushion is not a tire in the true sense of the word, and as it is protected on all sides it can be made much thinner than tires are usually made. The engraving represents a cross section of one half of the wheel.

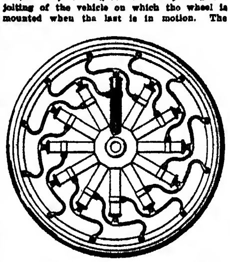
PNEUMATIC WHEEL.

ICE BREAKER.—J. L. OPP, Pinckneyville, Ill. This invention relates to devices for breaking ice from a cake, so as to serve a piece of any desired size and cause it to split on a substantially straight line. It is particularly adapted for embodiment in an attachment for ice wagons, but may be employed in connection with any suitable supporting frame at an ice plant, or the like.

VEHICLE WHEEL.—C. W. BARRETT, 158 Martin Ave., San Jose, Cal. The invention refers to wheels for use with automobiles and other purposes, and has reference more particularly to a wheel comprising a hub, a pneumatic cushion surrounding the hub, a felly, spokes connecting the cushion and the felly, and a solid cushion member within the pneumatic cushion.

VEHICLE WHEEL.—A. MCKILLOP, Alleghany, Cal. The inventor provides a resilient wheel which has the benefits of the ordinary pneumatic wheel, but in which the pneumatic member is not exposed to the wear of the ordinary pneumatic tire. The wheel has a series of pneumatic cushions disposed about the hub in such a manner as to take up shocks.

SPRING WHEEL.—A. W. DRUMMOND, Ap't. 56, Barker Block, Berkley, Cal. The rim is resiliently mounted with respect to spokes and hub, the object being to eliminate jarring and jolting of the vehicle on which the wheel is mounted when the last is in motion. The invention comprises a hub having a plurality of tubular spokes in which spring-actuated plungers are mounted, the plungers being pivotally connected at their outer ends each to a leaf spring connected at one end to the rim of the wheel and at the other end to the body of a spoke adjacent the spoke at which each plunger is mounted. A side elevation of the wheel is shown herewith partly in section.



SPRING WHEEL TO ELIMINATE JARRING.

NOTE.—Copies of any of these patents will be furnished by the SCIENTIFIC AMERICAN for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

Notes and Queries

Kindly keep your queries on separate sheets of paper when corresponding about such matters as patents, subscriptions, books, etc. This will greatly facilitate answering your questions, as in many cases they have to be referred to experts. The full name and address should be given on every sheet. No attention will be paid to unsigned queries. Full hints to correspondents are printed from time to time and will be mailed on request.

(12672) G. A. B. asks: If one pours hot water into a glass it often breaks, while if one puts a spoon in the glass first it seldom does break. Can you tell me why this is? What is the effect of the spoon in or on the glass that should save it? What is the scientific principle? A. The reason usually given why a glass does not break when hot water is poured into it, if a silver spoon be in the glass, is that the spoon serves as a conductor of the heat, and so the glass does not receive so severe a shock from the heat as it would otherwise. Silver is the best conductor of heat known, and therefore takes heat more quickly than any other material.

(12673) S. G. says: 1. Why is perpetual motion impossible? A. Perpetual motion is impossible because of the equality of cause and effect. The effect is never greater than its cause. There is no frictionless machine, and force is always required to overcome inertia in a machine whose parts have any weight. This being the case, some of the power imparted to a machine must be used in imparting motion to the machine itself, and in keeping it in motion. The rest of the power appears in useful work. This is always but a fraction of the total power imparted to the machine. No machine can, therefore, in any way generate enough power to turn itself and do useful work. It cannot even generate power enough to keep itself in motion continuously. 2. Does the law of gravity interfere with perpetual motion? A. The law of gravity is silent in regard to perpetual motion. It only specifies the manner in which matter attracts all other matter in the universe. It is simply a statement of a universal fact. 3. Has anyone reached the point of defying gravity? A. Anyone may defy gravity if he is strong enough. Every time you rise from a chair or climb a ladder you defy gravity. Aviation is a grand defiance of gravity. But if you mean that a man should rise without putting forth any exertion, and remain poised without support or effort, then our answer must be that no one has or ever will defy gravity, so long as attraction exists between the particles of matter. The constitution of the universe must be changed and become totally different from what it is at present for that to be done.

(12674) R. M. asks: Within the past few years we have had some very severe electrical storms, and my daughter's house has been struck twice by the lightning. We have been wondering why it should strike this particular house both times. It stands high and is 70 feet away from any other house. We do not think this the reason, because lightning strikes houses in valleys just the same. There is an attic over the entire house which is not plastered, and having a slate roof, the heat is intense. This attic is not used, as it can be reached only by a ladder. There are three windows in it, but of course it is not ventilated very often, and we have come to the conclusion that this hot, foul air attracted the lightning. We have broken a small pane of glass in each window, but this does not seem to help much. Have been thinking of putting a ventilator in one window. This would cause a current of air. If this is placed in the one window, would it be all right to have the small panes out of the other two? Would you advise placing shutters instead of the three windows? A. The matter of protection from lightning is a very perplexing one. It is certain that the old proverb, "Lightning never strikes twice in the same place," is not true. Some localities are more liable to be struck than others. The character of the soil seems to affect the liability to be struck. A recent writer makes the liability as follows: "If the liability for chalk formation is 1, then it is 2 for marl, 7 for clay, 9 for sand, 22 for loam." Some kinds of trees are more liable than others to be struck. In a study covering 45,000 acres in a German forest, it was found that oaks were struck 159 times; beeches, 21 times; pines, 20 times; firs, 59 times; birches, 4 times; larches, 7 times; and ashes, 5 times. The proportion of the different kinds of trees in the forest was: Beech, 70 per cent; oak, 11 per cent; pine, 13 per cent; fir, 16 per cent. These facts may assist you in judging whether the locality has anything to do with the frequency of the lightning strokes. As to the heat of the air in the attic, we have never heard of this as a cause of lightning striking, but it is best to ventilate the attic for its influence upon the health of the family in the dwelling. We should take the windows out on all the sides possible, and keep the rain out by a lattice blind during the hot weather, replacing the sash when cold weather comes on; but we should provide for ventilation all the year around. Some have thought that a current of hot air rising with the smoke from a chimney would aid to determine the path of a lightning discharge. This may be true. In such a situation as you describe, we should have good lightning rods placed upon the house. To go into this matter in detail is quite beyond the limit of a letter, and we would suggest that you ask the assistance of the weather observer at the station in your city. The Bureau in Washington has published much valuable advice on the installing of lightning rods, and they will be able to place this at your disposal at a very moderate cost. Fortunately, there are relatively few fatalities to human beings from lightning as compared with the large number of lightning flashes.

NEW BOOKS, ETC.

Physiography for High Schools. By Albert L. Arey, C.E., Frank L. Bryant, B.S., William W. Clendenin, M.S., M.A., and William T. Morrey, A.M. New York: D. C. Heath & Co., 1912. 8vo.; 450 pp.; illustrated. Price, $1.25.

Taking first the earth as a planet, and then dealing with its air, its sea, and its land, the collaborators in this text-book endeavor to impart to high school pupils a rounded knowledge of physiography. A great deal of care is evident in the selection and arrangement of material. That deemed advisable of omission from a first-year course is so indicated by being set in smaller type. Technical terms are italicised when first used, so that they may be the more readily mastered and defined by the student. The questions following each chapter require the use of the reasoning powers and the drawing of inferences, rather than a mere parrot-memory of the chapter material.

Sanford's Manual of Color. By John Ithiel Sanford. New York: Mrs. J. I. Sanford, 150 Fifth Avenue. 8vo.; 33 pp.; illustrated. Price, $1.

Rightly holding that the harmony of color should be recognized as quite as important to the eye as harmony of sound is to the ear, Mr. Sanford gives us a primer of the laws governing color and combinations of color, a primer that might be used to advantage not by artists and colorists alone, but by all who desire to dress tastefully and to have their home surroundings harmonious and pleasing. It is true that the writer forces us to relinquish that magic word "vibgyor," so lavishly made use of by the school textbooks of fifteen or twenty years ago, for violet is classed as diluted purple and indigo is discarded as being a combination of black and blue and hence impossible of inclusion among the prismatic colors. But the destruction of a few cherished beliefs should not blind us to the merits of the little primer, which gives within thirty-three pages a wealth of sound instruction and demonstration. Two color charts serve to make clear the rules and definitions, the "hexagon color guide," showing in a particularly simple way the relation of primary, secondary, tertiary, and intermediate colors.

Some Chemical Problems of To-day. By Robert Kennedy Duncan. New York: Harper & Brothers, 1911. 254 pp.; illustrated.

A rather forbidding title, this, for a collection of most interesting essays. One would imagine that the book was intended for the specialist, did not the author's name give a clue to the nature of the work, for Prof. Robert Kennedy Duncan is well known as one of the most entertaining of writers of real science for non-technical readers. Two of the chapters in the present work take the reader to the very extremes of chemical exploration, from the investigation of particles so small that millions of them together would barely be visible to the naked eye, to the study of enormous incandescent masses, so distant that the largest of telescopes fails sensibly to magnify them above a geometric point of light. From veriest childhood one has associated with the word "chemistry" a process of division by which eventually an individual molecule could be arrived at, a particle so small that it could not be further divided without surprising changes in its characteristic properties. The diameter was expressed by a decimal consisting mainly of a long string of zeros—whether a dozen or two dozen one could not quite remember. What was the use of burdening the mind with a theory? But those vague rows of ciphers now have a real meaning. The microscope, which at best could not detect an object smaller than one-seven thousandth of a millimeter in diameter, has been cast aside for the ultra-microscope, which enables one to see particles so infinitesimally small that if they are not actually molecules they certainly approach very closely to molecular dimensions. Better still, an apparatus has been devised for actually counting the myriads of atoms in a given quantity of helium. All of this is recounted in a most fascinating chapter on "The Question of the Atom."

From this point the reader is taken to the antipodes, where he finds the chemist collaborating with the astronomer in developing a new theory of the solar system and analyzing the constituents of a nebula countless millions of miles away, almost as if he had it in a test tube in his own laboratory.

Other frontier posts are visited in the chapters on the "Whitherward of Matter" and the "Chemical Interpretation of Life," and the reader is given a glimpse of two of the most fascinating phases of chemical research. The rest of the book pertains chiefly to problems of industrial chemistry: revolutionizing of the camphor industry; developments in bread-making, the relation between chemistry and manufacture in America, and the work of the industrial fellowships at the universities of Kansas and Pittsburgh.

The book as a whole is somewhat disconnected being largely made up of articles previously published in magazines, but each chapter is a complete story in itself, charmingly written in the author's familiar style.

My Three Big Flights. By André Beaumont (Lieut. J. Conneau). McBridge, Nast & Co., New York: 156 pp.; illustrated.

Lieutenant J. Conneau, who assumed the name of Beaumont for aviation purposes, and won fame as a result of his remarkable performances in the now historic races, "Paris to Rome," the "European Circuit," and the "British Circuit," has written a most readable and entertaining book on his experiences. Lieutenant Conneau, unlike most aviators, is a man of scientific training and therefore admirably qualified to guide a machine through the air. Unquestionably his success is partly to be attributed to his skill in navigating. Lieutenant Conneau has written in a very light vein, and makes no pretense to giving much technical information. But even as it is, there are glimpses here and there of the difficulties that must be coped with in handling a monoplane.

Internal Combustion Engine Manual. By F. W. Sterling, Lieutenant U. S. Navy. Annapolis, Maryland: School of Marine Engineering, U. S. Naval Academy, 1911. 8vo.; 146 pp.; illustrated.

The manual is intended as a textbook for the use of midshipmen, but there is no reason why other students should not profit by the well-arranged data here offered. Fuel being the fundamental that controls design and operation, this subject is first presented. After considering fuel, ignition, cooling, and lubrication in their relation to the engine, these four operations are shown combined in some of the latest and most approved types of engine. The producer plant is given a chapter to itself. For so short a course, the subject has been treated in a very sensible and satisfactory manner.

Studies in Terrestrial Magnetism. By C. Chree, M.A., F.R.S. New York: The Macmillan Company, 1912. 8vo.; 201 pp. Price, $1.50 net.

The "Studies" present Prof. Chree's original researches in certain branches of terrestrial magnetism, and the work makes no claim to being a complete text-book of its subject, or a summary of existing knowledge. Among other papers of interest may be mentioned those on secular and non-cyclic changes, on diurnal inequalities, on Antarctic magnetic results, and on comparisons of Arctic and Antarctic disturbances. It is suggested that more rapid progress might be made if educational institutions, equipped with the necessary instruments, would co-operate in a general plan of systematic observations. The invention of a more accurate and efficient magnetograph, free from "drift," is greatly to be desired. The author believes that it may become possible to differentiate between various types of sunspots, and thus to attain to a perception of some definite relationship between sunspots and magnetic storms, toward the existence of which relationship it is at present advisable to maintain an open mind.

Baseballogy. By Edmund Vance Cooke. Chicago: Forbes & Co., 1912. 16mo.; 88 pp. Price, 50 cents.

These rhymes of baseball deal most adequately with "Fan's taste, fan's talk, fan's dope, fan's everything." "Afflatus" is quite shamelessly rhymed with "tomatoes," "bucolic" with "base-ball-ic," and under such dignified captions as "Metempsychosis" and "Evolution" appears some of the most atrocious slang ever heard about the diamond. The verve and vim of Edmund Vance Cooke's well-known style pervades every stanza, and fans—especially those sufficiently educated to appreciate references to Socrates, Titian, and Achilles—will find many a chuckle in this timely epic of the national game.

False Modesty. By E. B. Lowry, M.D. Chicago: Forbes & Co., 1912. 16mo.; 110 pp. Price, 50 cents.

"False Modesty" is a little volume of instruction by the author of "Truths" and "Confidences." Its appeal is particularly directed to parents, teachers, and physicians, and calls for the wider dissemination, in pure form, of the knowledge necessary to save the young from the various pitfalls which ignorance of sexual laws places beneath their feet. Some appalling facts are made known, and it is the writer's belief that the country is as debased, in proportion to its population, as the city. Instruction in motherhood is urged as a partial solution of the problem. In a final chapter on "Coming Educational Reform," facts all too little known alternate with clearly-phrased advice and instruction of prime importance to the men and women of to-morrow. The need of education in the laws of sex and in sexual hygiene is characterized as the greatest need of American civilization.

Cutting It Out. By Samuel G. Blythe. Chicago: Forbes & Co., 1912. 16mo.; 60 pp. Price, 35 cents.

The Fun of Getting Thin. By Samuel G. Blythe. Chicago: Forbes & Co., 1912. 16mo.; 68 pp. Price, 35 cents.

In "Cutting It Out," "it" refers to the use of intoxicants. As the cutting out of intoxicants was also a feature of "The Fun of Getting Thin," it would seem that Mr. Blythe might have informed the public in one volume, at one and the same time, how to refrain from liquor and how to reduce flesh. In each case from thirty to fifty pages are taken up in talking about the author's indifference as to whether anybody follows his advice or not, while the actual plans offered may be summarized in six words. However, had the little books been limited to essentials, we should have lost many pages of dry humor and sensible philosophy; then, too, it is probable that, written in this serio-comic vein, the little homilies will reach and convince good fellows who would never dream of attending a temperance lecture or reading a book on diet.

Allgemeine Vererbungslehre. Von Prof. Dr. Valentin Haecker. Zweite Vermehrte Auflage. Mit einem Titelbilde, 133 Figuren im Text und 4 farbigen Tafeln. XII, 405 S. gr. 8 vo. 1912 M–10–, in Leinenband MII,–. Braunschweig: Verlag von Freidr. Vieweg & Sohn.

This book presents to the biologist, the physician, and the animal breeder results that have been obtained after twenty-five years' of investigation by students of heredity. The book is essentially practical in character, for, although the author seeks to trace back to the protoplasmic cell those inheritable differences which are the object of the eugenist's study, he devotes much space to the application of recent discoveries to humanity, to animal breeding, and to plant breeding. This is the second edition of the work, a fact which speaks eloquently for the favor with which it has met in Germany.

Handbuch für Heer und Flotte. Enzyklopädie der Kriegswissenschaften und verwandter Gebiete. Herausgegeben von Georg von Alten, Generalleutnant z. D. Unter Mitwirkung von mehr als 200 der bedeutendsten Fachautoritäten. Vollständig in 108 Lieferungen reichillustrierten Textes mit farbigen Beilagen, Karten, Planen, Gefechtsskizzen usw. Leipzig: Richard Bong & Co., 1912.

Installments 41 to 44 of the Handbook for Army and Navy treat the subject from *Maximilian I to Napoleon I*. Among the articles that should be particularly mentioned are those on the extra-European Colonial Wars (1500 to 1648), the wars of the Swedes, Prussians, and Poles for the possession of the Baltic provinces, and the Thirty Years' War. This last subject is discussed on the basis of entirely new investigations. Most interesting is Dr. Koser's essay on the Wars of Frederick the Great. General Count Schlieffen has discussed admirably the Napoleonic campaign of 1806-1807. There are twenty-five excellent war maps on which may be found every geographical name mentioned in these installments.

The Evolution of Animal Intelligence. By S. J. Holmes. New York: Henry Holt & Co., 1911. 296 pp.

In this book the reader will find summarized in a very popular and interesting way the main results of recent psychological and chemical study of animals. Loeb's work on tropisms is commented upon at considerable length, as it deserves to be, since it is a serious attempt to explain by chemical action alone movements hitherto rather vaguely ascribed to "instinct." On the psychology of animals the author has dwelt at considerable length, particularly on the work done more recently by such investigators as Thorndike. About one half of the book is devoted to an explanation of the more or less automatic movements of the lower organisms, and the other half to the subject of intelligence itself. An excellent feature of the book is the bibliography appended to each chapter.

Heredity in Relation to Eugenics. By Charles Benedict Davenport. New York: Henry Holt & Co., 1911. With 175 illustrations and diagrams, and complete bibliography and index. 8vo.; 298 pp. Price, $2.

Dr. Davenport may be regarded as the leading exponent in this country of the science of eugenics. He has done able work, as the head of the Cold Spring Harbor Station, in rousing the public conscience to the subject of human heredity. The discussion of such cases as that of the famous Jukes family in America and the Zero family in Switzerland has unquestionably served to drive home the consequences of a too promiscuous mating of the socially unfit. Although it is much too early to pass any legislation which would have for its object the purging of the bad blood now in human society, books such as this on human heredity perform the useful service of keeping the subject before the public and of indicating how far science has progressed toward the solution of a problem which is nothing more or less than the preservation of the human race.

Dr. Davenport is a strict Mendelian. Although like most eugenists he acknowledges the merit of the early work done by Galton, the biometric method evidently has no attraction for him. Because it deals with groups rather than with individuals, the biometric can hardly lead to a definite solution of the eugenic problem. The Mendelian method, to which this book is largely devoted, has the distinct advantage of enabling one to determine with certainty how certain tendencies are transmitted. It is known accurately how such physical and mental defects as *dementia praecox*, Huntington's chorea, deaf mutism, etc., are inherited. The effort which Dr. Davenport has made to carry the investigation further, for example, to the inheritance of specific diseases (rheumatism, skin diseases, and diseases of the blood), while not wholly successful, as he himself admits, nevertheless indicates the wonderful possibilities which lie dormant in the method, if we only could gather sufficient facts and accurate family histories.

The New Serum Treatment of Bleeding and Hemorrhage

By Dr. Leonard Keene Hirshberg, A.B., M.A., M.D. (Johns Hopkins).

THAT the injection of fresh blood serum is a potent factor in controlling certain types of hemorrhage where there is a delay in the clotting of the blood, has been reported by a great number of scientific investigators.

The treatment of hemorrhage depends upon two factors: First, the use of drugs for their action on the blood vessels; secondly, agents used to promote the clotting of the blood itself. Many different kinds of drugs, whose value depends upon regulating the tension of the blood vessel have been used Among them are the salts of calcium, strontium, magnesium, and solutions of gelatin.

In 1910, an investigation of the causes of twelve cases of hemophilia, which is a certain type of disease with continuous hemorrhages, were published. The coagulation or clotting of the blood was long delayed, in all of these cases and in those patients who showed the most marked symptoms, clotting or coagulation required an hour or more.

Two forms of hemophilia were discovered, the accidental or transitory, and the congenital variety which appeared at birth. In the former the blood was thin and flowed rapidly through a needle inserted into a vein. In the latter, the blood was found to be sticky and it flowed slowly, very much like molasses. Experiments with blood were carried on, showing that if three drops of animal blood serum were added to three cubic centimeters of blood in either class of patients, the coagulation of blood took place promptly and hemorrhages ceased. They also discovered that the same effect could be produced by internal injections of the blood serum. The serum of a man, rabbit, horse, or ox was all found to effect a quick clotting of blood, previously conductive to hemorrhage. The value of this finding is appreciated, when it is realized that bleeders or "hæmophilics" are as common as club feet.

The serum was injected into a patient before the extraction of a tooth, and during an operation upon an abscess, and it successfully prevented every vestige of hemorrhage. As one doctor says: "Fresh serum is an effective remedy for the arrest of hemorrhage in all cases of blood disease. It is more effective than any previously discovered method to prevent general bleeding"

In applying the use of the serum, large doses must be employed, and that while any serum may be used, that of the ox or goat should, if possible, be avoided, since it has the power to produce toxic symptoms of a serious nature The use of injections of animal blood, to prevent hemorrhage is permitted only in cases of real bleeders disease called "hemophilia." Many failures were reported due to attempts to apply blood serum to other diseases

An eminent scientist at work on this problem says that an injection of fresh serum is the most efficient means we have for the treatment of hemophilia, but if it is not at hand, regular antitoxic serum, whether diphtheria or lockjaw antitoxins, may be employed, and answers just as well.

There is a case of a boy of fourteen years who always had hemorrhages from the nose and gums which failed to respond to the treatment of injections of gelatin solution, but which stopped when injections of diphtheria antitoxin were applied. There is another case of a newly-born infant who had hemorrhages from the mouth and nose. The infant was treated by applying sponges dipped in horse serum, which rapidly controlled the bleeding.

Here is a typical case of hemophilia. A child, who was in a very poor condition as the result of a steady loss of blood following the extraction of a molar tooth, was treated by the application of astringent medicines, but they proved absolutely useless, so it was decided to try the administration of serum. Normal horse serum was injected, and after a few minutes the oozing blood became less and less and the bleeding stopped. There was a recurrence and relapse, however, and another injection of horse serum was given the following day. At once the hemorrhage ceased and did not reappear any more.

A striking report of the use of serum in treatment of hemophilia is afforded by a New York pathologist. He injected normal human serum in the treatment of nine babies. He believes that all of these babies would have died under any other treatment.

The following conclusions have been obtained by different workers:

1. The coagulation period in hemophilic subjects or "bleeders" is greatly shortened by the injection of fresh serum.

2. The local application of fresh serum in wounds, in patients in whom there is a delayed coagulation of the blood, acts as a preventive of hemorrhage.

3. The serum of any living animal species is efficient in producing this phenomenon of clotting.

4. The sera of the ox and dog should be avoided if possible, because of the toxic symptoms frequently attending their use.

5. Regular tetanus and diphtheria antitoxic sera are less satisfactory than freshly drawn material, but do very well in an emergency.

The difference between antitoxic and fresh sera may be due either to age or to the presence of the preservative drugs, which the former always contain. The reports that antitoxic sera have been effective in some cases and disappointing in others is due to the fact that age or drugs act as a retardant to clotting. The inactivity of the sera probably depends upon the changes which they undergo with age.

The belief that the action of animal or human serum in increasing the coagulation of blood in hemophilic subjects depends upon the substitution of an active clotting agent is, therefore, based upon the following facts:

The rapidity and completeness of coagulation is directly proportional to the amount of this complicated clotting agent found in the serum that is introduced. This agent is called "thrombin," and is about the same as the pepsin in the stomach.

Experience shows that relatively large amounts of serum must be employed to produce definite results. That is to say, to stop bleeding in anyone, it is essential that large quantities of new blood serum be introduced into the veins of the one who is suffering the hemorrhage. It is worse than useless to give a little serum: a great deal or none at all must be given.

To Dr. Alexis Carrell, Prof. William H. Howell, and Dr. Crile, all young American scientists, the public are indebted for discoveries that have lead up to this great new method of life-saving. With antiseptics, antitoxins, anæsthetics, aeroplanes, spectrum analysis, radium, X-ray, wireless telegraphy, telephones, the Panama Canal, and synthetic chemistry, the serum treatment of hemorrhage and bleeding, will be soon placed among the modern wonders of the world.

Can the Baser Metals Be Changed to Gold?

THE newer scientific contributions from the physical, chemical, and electrical laboratories, work from discovered and confirmed facts to widely applied theories. This is in marked contrast to the science of the schoolmen and the ancients, who ponder deeply in a high attic, evolve some kind of a theory, and then discover only such facts as conform to their pet theory.

This difference is much more marked than the man in the street is willing to admit. It is a contrast that many boast-

ful "self-made" men do not see. The investigations of radio-activity and electrons, have proved beyond cavil that the elements are not immutable. They are essentially all alike at bottom, and are made by an evolutionary process.

It is known to every high school student that the element radium, spontaneously disintegrates into two other elements; one a heavy, inactive gas called niton, and a lighter gas called helium. In turn, after niton has emanated from radium, it changes into helium and a solid element, until recently called radium A. Radium A also undergoes disintegration into other elements, and so on *ad infinitum*. Each one of these breaking down experiments sets free enormous quantities of energy; enough, in fact, to make electricity for a large city. It has been carefully calculated by Sir William Ramsay and his co-workers that the decomposition of one cubic centimeter—about a thimbleful—of niton, is accompanied by the evolution of some four million times as much heat as is obtained by burning an equal amount of gas.

It is thus clearly apparent that as each element and its atoms disintegrate, they unlock and liberate a reservoir of potential energy so immense that the finite mind of man cannot grasp it. Once this vast effort of nature is realized, it will begin to be faintly understood, how much power will be necessary to generate the excessively high potential requisite, to change or transmute one metal element into another; base tin into virgin gold, as the alchemists attempted. The only energy of this sort available is that given out with the natural breaking up of niton and the other radio-active elements; and even then because of the long periods required, the slowness of the change, the transmutation even if possible, only infinitesimally small particles of elements would ever be transmuted.

Sir William Ramsay recently performed certain experiments in this direction on distilled water and niton. Mr. Cameron assisted him in this work. Distilled water, upon which a very small amount of niton gas was allowed to act, was placed in a silica glass tube. Then the gases which resulted were removed, and examined with a spectroscope. Hydrogen, oxygen, helium, neon, and niton were found. They concluded from these experiments that the transformation of niton into neon in the presence of distilled water as indisputably proved, and, if a transmutation be defined as a transformation brought about at will, by change of conditions, "then this is the first case of transmutation of which conclusive evidence is put forward," Dr. Ramsay writes.

Sir William Ramsay and Mr. Cameron no longer maintain in the face of Madame Curie's disproof, that lithium can be transmuted from copper. The work of Sir William Ramsay with Mr. Usher on the action of niton upon solutions of lead, thorium, titanium and silicon, where carbon was always previously excluded, showed the presence of carbon dioxide every time. Chlorate of bismuth and zirconium solutions, showed carbonic acid gas also when acted on by niton.

But in no case so far discovered, was an element obtained by such transformations that were heavier than the elements from which they came. No experiment has yet been successfully carried out by Sir William Ramsay or by any other physicist, in which an element became changed into one of higher atomic weight. Even criticism of such transmutations as have been obtained, were made. Rutherford held that the neon and argon found, might have come from the glass or leakage, but the quantities reported certainly disprove any such possibility.

Loath as we have been to give a place in modern chemistry to the doctrine of transmutation of elements, little as we care to seriously consider attic theories, dogmas dear to the hearts of the advocates, near-new philosophy, or chemical divining rods, none of us can deny these established, laboratory facts, repeatedly confirmed by unbiased experimenters.

Hence, the volatile imaginings of that vapory crew of pseudo-chemists of the

Middle Ages, although founded upon vain dreams and their illogical yearning for a philosopher's stone and an elixir of life, the modern physicists now stand sponsors to the ghostly nothings of medieval alchemy.

The Aeroplane in the Military Maneuvers

(*Concluded from page 156.*)

above a height of 2,000 feet. If the barograph showed that they had dipped below this level they would be counted out, having been theoretically shot. German regulations place the safety zone above 2,800 feet, and French regulations above 3,000 feet. Considering the fact that the men had to use both hands for the control of their machines, and, therefore, could not employ field glasses to study the country beneath them, the reports they turned in were marvelous in detail and accuracy. Lieut. Foulois, for instance, in his reconnaissance of August 18th, left camp at 3.58 A. M. and returned to camp at 10.28 A. M. The report he brought back covered two typewritten pages, and gave the location of thirteen different military bodies. All the time he was making tests with his aeroplane wireless set. No actual messages were sent, but various letter signals were transmitted, for the purpose of attuning the instrument. Lieut. Milling also brought back a very complete report, which was even more detailed than that of Lieut. Foulois, for the reason that he was not handicapped by attention to a wireless telegraph instrument With his high speed machine he made the circuit in a little over an hour and brought back detailed information that would have taken half a day for an entire brigade of mounted scouts to have collected As yet the relative accuracy of the report obtained by mounted scouts and those obtained by aeroplane scouts have not been made public. However, the chief umpire knowing the exact position of every detachment was able at once to confirm the accuracy of the aeroplane reports.

The officers have expressed themselves as highly pleased with the work of the aviation squadron. It must be borne in mind that the country over which these operations have been conducted is the most difficult flying country imaginable. There is no level ground anywhere. It is so cut up with valleys and gorges that the air fairly boils with unexpected gusts of wind

Although Mr. Haven is an accomplished and daring aviator, his work so far, as a scout has been very disappointing. While the other scouts have brought back two-page typewritten reports, he has been able to discover practically nothing of value. It has been urged that the United States Army does not need to go to the expense of establishing an aviation squadron for the reason that there are so many experienced aviators in this country who could be hired in time of war to do the scouting for the army, and if they were unable to report any information themselves, they could at least carry a passenger with them. The present maneuvers show that the carrying of passengers is by no means feasible under all conditions, and unless the aviator is able to make a detailed report, the army is likely to suffer from lack of important information.

While the aviation squadron has done splendid work under the peculiar conditions encountered, nevertheless the fact has been clearly demonstrated that what the army requires is a well trained corps of aviator scouts with machines not necessarily of high speed, but certainly of large carrying capacity, which will be capable of rising from the ground under the most adverse conditions. It is quite essential that a machine carry a passenger because it is impossible for a man to pilot a machine and keep track of all that is passing beneath him, trusting to his memory largely with only an occasional opportunity to reach over and jot down a few words of memorandum.

If this branch of the service can be fully developed, it will no doubt result in great economy, for it will make it unneces-

sary to employ mounted scouts, thus leaving the cavalry free for fighting purposes only. Of course in these maneuvers the aeroplanes have had no enemy in the air to contend with. During the first half of the maneuvers, that is, in the instructional period, the aviation squadron was neutral. After that the machines were divided between the two armies. They were perfectly safe from attack as long as they kept above the danger zone, but in time of war no doubt they would have to contend with aerial sharpshooters.

The work of the wireless set on board Lieut. Foulois's machine was purely experimental, and nothing much was done. The instruments he used were selected and installed by himself on the machine. A small generator capable of developing 250 watts was driven by friction gearing from the flywheel of the engine. He used the wire bracing of the aeroplane for a counterpoise, and for his antenna he employed a suspended copper wire 300 feet long. This he paid off from the machine gradually after he had reached a sufficient elevation. His sending key was attached to one of the operating levers. The only one available was that on the left hand side, and it was necessary for him to send his signals by operating the key with his left thumb. This was exceedingly awkward, and the signals he sent were certainly not of the best. Nevertheless, they were clearly picked up by the wireless station at headquarters, even when the aeroplane was over twelve miles away. When landing, Lieut. Foulois clipped the wire before it had come within reach of trees or other obstruction on the land. The release of the antenna was effected very accurately, and it always dropped within a prescribed area, so that it was readily recovered.

Antagonistic Body Juices

THE substance produced by the "suprarenal capsules," small bodies lying just above the kidneys, plays an important part in the workings of the higher organisms, since death quickly follows the removal of these bodies. At the same time, the exact function of the substance is not known. If a small quantity of the adrenalin, or extract from one of these capsules is injected into the blood, there is a quick rise in the blood-pressure. This is brought about by the contraction of the muscles of the smaller arteries. The effect lasts but a few minutes, however, and at the end of that time it is quite impossible to discover a trace of the adrenalin in any part of the blood. What becomes of the adrenalin in that short time is a complete mystery.

Many poisons and other foreign substances are destroyed or neutralized directly by the blood, but that is not the case with adrenalin. If a small quantity of the substance is mixed with blood and the mixture is allowed to stand, the adrenalin may still be discovered the next day. Neither is it destroyed by any sera.

Within a very short time, however, Dr. S. J. Meltzer of the Rockefeller Institute has discovered that there is a body fluid capable of destroying adrenalin. Dr. Meltzer had an opportunity to obtain quantities of spinal fluid from a number of patients suffering from various diseases. In all cases the adrenalin was destroyed by the spinal fluid within an hour, if kept at the temperature of the blood. If the mixture of the two fluids was kept in an ice-box, however, the adrenalin was just as active at the end of a long time as it was when first prepared. One part of the adrenalin was mixed with twenty parts of spinal fluid, and one half cubic centimeter was used as a test, the effect of the mixture upon blood-pressure in a frog being an indication of the activity of the adrenalin. If the mixture is kept warm, even four times the normal dose produces no effect at the end of an hour.

In some diseases the spinal fluid is much more active as a destroyer of the adrenalin than in others. Thus the spinal fluid from a patient suffering from infantile paralysis is quicker in its action than the spinal fluid from one having tubercular meningitis. This fact may turn out to be of great practical importance, in the opinion of experts.

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are *sharp*, the articles *short*, and the facts *authentic*, the contributions will receive special attention. Accepted articles will be paid for at regular space rates.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

Relative Sea Strength of the United States

ACCORDING to the latest estimate made by our admirable Office of Naval Intelligence of the Navy Department, the United States has already yielded the position of second in naval strength among the navies of the world to Germany. This is true, even if we take into consideration the battleships already built, and it is startlingly true, when we consider both the battleships built and those under construction. At the present time Great Britain possesses fourteen battleships of the dreadnought type, Germany eight, and the United States seven. Great Britain has eleven such ships under construction, Germany nine and the United States five only. In battleships of the pre-dreadnought type, such as the "Connecticut," "Georgia" and "Maine," Great Britain possesses forty-one, Germany twenty-one and the United States twenty-five, which gives us a superiority of five ships of this class over Germany. The pre-dreadnought battleships, however, because of their inferiority in speed and gun power will be at a great disadvantage when they come to lie in line of battle against the modern ten- and twelve-gun dreadnoughts. Even on a basis of the total tonnage of all ships completed, Germany still has a decided lead over the United States. Great Britain heads the list with 1,888,414 tons, followed by Germany with 787,709 tons, the United States with 758,491 tons, France with 619,512 tons, and Japan with 438,087 tons.

When we come to consider the vessels which are now under construction, the great activity of Germany and the comparative inactivity of this country produce a marked difference in the comparison. If all vessels now building were completed, Great Britain would lead with 2,469,678 tons, Germany would be second with 1,140,238 tons, and the United States would be third with 914,744 tons, France would come next with 804,211 tons, and Japan fifth with 617,083 tons. Of dreadnought battleships and battle cruisers combined, Great Britain would possess thirty-six, Germany, twenty five, and the United States, twelve only—less than one half the strength of Germany, and just one third the dreadnought strength of Great Britain.

In the presence of these figures, it is simply bewildering to attempt to understand the attitude of the House of Representatives in its attempt to prohibit the construction of more battleships. In one single week Congress has seen fit to reaffirm the Monroe Doctrine and to repudiate the pledges of a treaty, the ink of whose signatories is scarcely yet dry. Statesmanship of this kind can scarcely be called pacific. If it is the policy of Congress to tear up treaties and cry "hands off" from the only promising field remaining for colonial exploitation, this policy should surely be backed up with those armed forces which are necessary to render it successful. We believe there never was a time when the United States so greatly needed a strong navy as she does at this critical stage of her progress toward her ultimate dominant position among the world powers.

America's Need for an Aerotechnical Institute

THE inventors and builders of air craft in this country feel keenly the want of experimental data to form a rational basis for their structural designs; the users and students of air craft experience an equal want of adequate and disinterested comparative tests of existing craft, appliances and accessories. There is, therefore, a general desire for an American aeronautical institute that shall meet these wants in the broadest and most thorough manner, an institute not for training aviators or instructing engineers, for this is already done in several places, but primarily for producing and disseminating aeronautical science.

In European countries some excellent laboratories for aeronautical research are privately endowed and conducted in the interest of civil science and construction; others having governmental support are intended primarily to subserve a military purpose and may not be readily available, if at all, for civilian use. The latter kind are, at present, not strongly demanded in this country, either by the army or the navy. Hence, if a federal appropriation for the advancement of aeronautical science be made at all, it should be alloted to one of the civil establishments, such as the Bureau of Standards, or the Smithsonian Institution. The latter can receive both private endowments and federal grants, has sufficient building space, an aeronautical library and the old Langley workshops, not to mention the Hodgkins fund of $100,000 for studies of the atmosphere.

If an aeronautical institute were privately founded it should have an endowment equal at least in purchasing power to the best in Europe, say twenty to thirty thousand dollars a year; its directorate should include representative men alert to the needs of aero science and industry; it should be practically independent in its finances and government, or if affiliated with a great seat of learning, should not be dominated by the president or teaching corps, or in any sense made a dependent of, or mere adjunct to, some scientific department.

Whether established by private means or governmental, or both, what our people require is a representative American institution "in which a staff of trained specialists, provided with adequate apparatus, shall furnish physical constants, laws, formulæ, and empirical data of substantial and permanent value to the engineer, the inventor, the manufacturer, whose energies should remain free to employ such knowledge to the advancement of important industrial arts; a laboratory where complete and reliable tests and reports shall be made upon all classes of actual air craft that may be worthy of study and development; an institution surrounded by ample maneuvering space of land and water, and preferably adjacent to a governmental flying ground, available with hangars and shops, to all civilians worthy of assistance; a center of scientific and practical activity, where at all times may be witnessed the most accurate researches and most exhaustive tests; where the knowledge so gained shall be disseminated by publications, by oral communications, by exhibitions of apparatus and instruments, of materials and models, by photographs and drawings, in a word, by all the facilities of the aerodrome, the show room, the library, and the assembly room."

The foundation of a national institute so comprehensive and thoroughgoing would greatly promote a direct and universal mode of locomotion, and would constitute a monument fit to bear the name of the most munificent patron of science. But unless an individual will endow such an institution adequately to meet all requirements for many years, it will be better for the votaries of aeronautics to initiate an establishment comprising such buildings and endowment fund that it shall be capable of ample growth by the cumulative contributions of many individuals or associations, and by occasional grants from the federal government. Better no aerotechnical institute than one too meagerly furnished with men or resources to meet the practical needs of the community and to make substantial contributions to the science in which America once enjoyed leadership.

Hon. W. G. Sharp, in an able appeal to the House of Representatives for the encouragement of aviation, recommended an appropriation for an aeronautical laboratory, and the Aero Club of America has, with the indorsement of prominent scientific bodies, pledged itself to secure the endowment of such an establishment. The SCIENTIFIC AMERICAN commends the movement most heartily.

The Possibility of the Oil Engine

THE internal combustion gasoline engine is being developed as much in the United States as elsewhere, and the Junkers oil engine, the most recent challenge of the reciprocating heat motor, may be expected to have a great career on this side of the Atlantic. Occasional oil engines in electric central station service—Diesel engines—are already reported, and any class of engine room attendant can operate them successfully.

For marine propulsion also, who knows but the staunch ships that will some day be launched to revive the ancient glory of the American merchant marine will be equipped with oil engines. Our own fuels and those of Europe and Asia [illegible] vessels, with the great oil fields of other parts of the globe to fall back upon, including the vast supply in Borneo. Oil is the coming fuel for propelling vessels. It is cheap, it saves space and weight, it requires a smaller crew, and it is incomparably preferable to coal in point of cleanliness. Roughly speaking, in the oil engine one ton of oil equals 3½ tons of coal, the economy being higher as the size of the engine is increased. In order to compete with oil, coal must be obtainable at thirty-nine cents per ton. As a power auxiliary for sailing craft the new engine should find a great field where steam has not had a very extensive application owing to the inconvenience of rigging a temporary funnel, the long time required to get up steam in an emergency, and the valuable cargo space taken up by the coal bunkers and the boiler. The oil engine, on the other hand, is always ready for instant use, no funnel is required, the space taken from the cargo capacity is but a small part of the whole, and the oil fuel can be stowed where it would be impracticable to carry coal. While these advantages are shared by the gasoline auxiliary, the new oil engine leads in the far lower cost of its fuel, in the extreme simplicity of the engine, seldom necessitating repairs or overhauling, the absence of any ignition mechanism, differential or reverse gear, and the excellent cooling system.

The Needs of the Bureau of Chemistry

WHAT shall be said of the powerful division chiefs in the Bureau of Chemistry, who, charged with safeguarding the health of ninety million people, fail to gather scientific evidence of a character that would enable the courts to bring dishonest food manufacturers, criminal dispensers of injurious beverages, and adulterers of healing drugs to book? And what shall be said of a government that permits a Bigelow, a Kebler and a Doolittle to squander public money in worthless analyses and to bring actions that any open-minded lawyer must know are futile? Only the press can rouse the public to a sense of the grave risks incurred by the maladministration of the Pure Food and Drugs Act for which these three men are largely responsible; but the public press knows nothing of science and publishes nothing but praise of the inept officials who control the Bureau of Chemistry.

The organization of the Bureau is in part responsible for a situation which has made scientific work almost impossible. At present those who are charged with the investigation of food and drug products are subject to the authority of Bigelow and Kebler, of officials, in a word, in whose hands mainly lies the fate of the Food and Drugs Act. What could be more admirable? Is not this the practice of every manufacturing establishment? It so happens, however, that the Bureau is not a department store, where such a system might operate well, but a scientific institution, intrusted with highly important investigations that concern every man, woman and child of the ninety million people who constitute the population of this country. And it so happens that the division chiefs or their agents prosecute manufacturers for violations of the Pure Food and Drugs Act, not as scientific men, absolutely sure of their facts, but as district attorneys. Like district attorneys, they care only for the game of prosecuting, and measure their efficiency rather by the number of actions brought than by the character of their scientific work.

Under the present system the subjects for investigation are assigned to subordinate officials by the very division chiefs who are eventually to prosecute manufacturers guilty of fraud. The success of the division chiefs in court depends on the scientific findings of those who are assigned to the cases. If the division chiefs were men of any scientific standing, men who cared only for the scientific facts, the system might still be effective. But, caring chiefly for prosecutions and little for scientific truth, it can be imagined how little they care for research. The public is vitally interested in the proper enforcement of the Pure Food and Drugs Act, and consequently in the scientific investigations of the Bureau of Chemistry.

Waste in Paper-making.—Chemists attribute the great rise in the price of all sorts of paper in recent years largely to wasteful methods of manufacture, which for the most part the mills care little or nothing about checking. One well-known chemist said the other day: "Some years ago I made a contract, after much trouble, with a large paper mill. The first thing I did when I went to work was to collect samples of all their waste waters and determine the amount, proportion and kind of material that was going into the stream. This mill had never paid, though it was well located. One reason for their failure to pay a dividend, I found, was that 17 per cent of the product was floating off down the river. I told the manager about it. Well, he paid my salary for a year, and never allowed me to come into the mill again."

Electricity

German Regulation of Wireless Telegraphy at Sea.—The new official regulations, requiring all German passenger steamers carrying a minimum of 75 persons, including the crew, to be equipped with wireless telegraph apparatus of a transmitting radius of 100 nautical miles, will go into effect on October 1st.

Heating Churches by Electricity.—Owing to the large amount of water-power in Switzerland, electricity can be applied to a good advantage and a low cost, for heating buildings, and it is stated that it is also being used in a number of instances for the heating of churches. Among these are the churches of Walfhalden, Schwellbrunn, Arosa, Sils, Brugg, Aengst and others.

Sweden's Hydro-electric Development in 1911.—The newly-erected hydraulic plants in Sweden for the last year amount to nearly 40,000 horse-power, and to this is to be added the extension made in the former plants during the year, which makes a total increase of 67,667 horse-power as against 62,385 for the preceding year. These figures relate to electric power plants installed by private companies. The height of the fall which is used here varies up to 240 feet, and in general it is under 80 feet.

A Large Electric Plant in Brazil.—A company has recently been formed for the purpose of constructing an electric power plant in Brazil which will be one of the largest in South America. The hydraulic station is to be located on the San Francisco River and the power will come from the Alphonso falls. It is stated in the French technical journals that the size of the plant during the initial period of operation will be about 200,000 horse-power, but at a later date the station may be extended so as to produce as much as 1,300,000 horse-power.

Pekin's Telephone System.—The telephone service of Pekin has been commenced by the installing of two central exchanges which are laid out for a total of 6,400 subscribers. There are about 3,000 subscribers in the Chinese and the Tartar quarters, and the remaining quarters are to be wired up at a no very distant period. It is to be noted that the two exchanges are constructed by the government and are now being operated by it. The legations already had many private telephones, and these are now connected to the above exchanges.

Wireless Telegraphy From Balloons.—A German experimenter, H. Mosler, has devised a method of using wireless telegraphy upon spherical balloons. He places a wire around the balloon body so as to form a vertical loop, also a second wire hanging down from the basket. More recently he has found it best to attach the loop wire to a band of stout canvas and then to lay this around the balloon bag so as to attach the band to the network and avoid putting the wire directly upon it as this might cut into the balloon. It is much better to have the loop lying to one side and not directly over the center, so that the wires coming together into the basket are away from the gas valve and are less likely to cause a fire.

Electric Steel Production in Norway and Sweden.—In Norway and Sweden there is considerable activity at present in the way of electric steel production. There are two new steel works with electric furnaces shortly to be erected which propose to turn out 16,000 tons annually during the first period, and this will no doubt be increased later on. One of these enterprises is carried on by the Stavanger Steel Company, which is capitalized at $1,200,000, and it is now arranging to secure 2,500 horse-power in electric current from a local hydraulic plant. The new works will include an electric furnace of the most recent design for steel production, with a rolling mill, steam hammers and foundry for steel casting. It is expected to turn out annually 1,600 tons of rolled steel, 300 tons forged steel, 600 tons cast steel, and 700 tons diverse. The second enterprise consists of an electric steel plant near Arendal and it will use current from the Boilejos hydraulic plant.

The Electric Furnace and Ferro-silicon.—The electric furnace process can be used to a great advantage in obtaining compounds of iron and silicon or ferro-silicon, and it is even possible to produce pure silicon in this way. The usual blast furnace methods are said to give a maximum of only 20 per cent silicon in the compounds obtained, but much more is given by the electric process. Besides, the impurities such as calcium, manganese, carbon and others are much less than before. It is noticed that ferro-silicon containing less than 30 per cent or more than 65 per cent is stable, but products lying between 30 and 65 per cent are easily decomposed. From a chemical standpoint it is admitted that there are at least three different silicides of iron, and perhaps two others. The present process is now being operated in Europe and is covered by patents, the electric furnace somewhat resembling a calcium carbide furnace, but it is found that a large-sized furnace is essential to obtain the proper results. Such must also be operated near to the center of raw material, with good transport facilities for the finished products.

Science

Drinking Cups For Horses.—The New York Bureau of Municipal Research announces that hereafter individual drinking cups and shower baths are to be used. The Bureau points out that among the 90,000 horses that perish every year in Manhattan no less than 6,500 succumb to glanders which is communicated by filthy horse troughs.

The Death of Schleyer.—On August 20th there died at Constance, Baden, Johann M. Schleyer. In 1879 he invented Volapuk, an artificial language that was as much spoken about in its day as Esperanto is now. His Volapuk was the first artificial language that attained any measure of practical success. When the third Volapuk Congress was held in 1889 two hundred and eighty three societies had been formed in various parts of the world to spread its use.

Prof. Frost Receives a Degree from Cambridge.—Prof. Edwin B. Frost, the director of the Yerkes Observatory, while a delegate to the 250th anniversary of the Royal Society was given the honorary degree of D.Sc. from Cambridge University. Prof. Frost will spend the year abroad in England and Germany. In his absence, Prof. S. Alfred Mitchell will be at Yerkes Observatory, having been granted a Sabbatical year for that purpose by Columbia University. Prof. Mitchell is well known to our readers from his contributions to the SCIENTIFIC AMERICAN on astronomical subjects.

Barring Insects.—On August 10th the House of Representatives passed a bill introduced last May by Representative James S. Simmons of Niagara Falls, N. Y., regulating the importation of plant products Under this bill it will be unlawful for any person to import into the United States any nursery stock except under permit from the Secretary of Agriculture and under conditions and regulations prescribed by him. The United States is the only great power without protection from importation of insect-infested or diseased plant stock. Diseased livestock is excluded by law, but diseased plants, have as yet, not been barred

The Origin of Novæ.—In the monthly notices of The Royal Astronomical Society for June, 1912, Prof. E. E. Barnard of Yerkes observatory has a paper on "Micrometrical Measures and Focal Peculiarities of Nova Lacertæ (Espin)." In the course of his paper, Prof. Barnard objects to the theory that the outburst of a nova is due to a star colliding with a nebula. He points out that photography does not show that the novæ are in nebulous regions except in the case of Nova Andromedæ and "even here the spectroscope throws doubt on the nebulosity." Prof. Barnard believes that we are probably dealing with real motion caused by some force not yet known. "Indeed," he assures us, "I think this, like some of the abnormal phenomena of the comets reveals to us the effects of new forces (call them that if you like) as yet unknown to us, but which we must take into consideration, as our knowledge of the universe advances."

A Catalogue of More Than 100,000 Stars.—At the Harvard College Observatory the most extensive astronomical labor ever undertaken is now in progress. Up to the present time, the largest and most complete star catalogue in existence has been the Draper Catalogue, which indexes about 10,000 stars, with careful details concerning their spectra. This catalogue was compiled by Mrs. Williamina Paton Fleming at Harvard before 1891. Since that year, the increasing size of telescopes and improvements in stellar photography have so greatly increased the number of stars shown upon the photographic plates that an entirely new edition of the Draper Catalogue, enlarged, and giving the record of each star to recent years seemed imperative. Prof. Edward C. Pickering, Director of the Harvard Observatory, has contemplated such an edition for many months, and in October, 1911, the work was begun. Since Mrs. Fleming's death in May, 1911, Miss Annie J. Cannon has been appointed Curator of the Astronomical Photographs, succeeding Mrs. Fleming, and Miss Cannon is in charge of the catalogue work. She is directing its progress so ably that what several distinguished astronomers feared they might not live to see accomplished, will probably be completed within five years. She has organized the research into divisions and sections, each of which is conducted by one or other of her women assistants. A vast collection of stellar photographs, giving a complete record of the heavens during many years, is available at Harvard through the co-operation of its Cambridge and Arequipa stations, so that abounding material is furnished for the catalogue. The work represents an infinite series of mathematical calculations, preliminary card-cataloguing, notations, charting, etc., which depends upon the utmost care in studying and comparing photographic plates, identifying stars, and determining their degrees of brightness, qualities and classes of spectrum. For such work women, says Prof. Pickering, have proved their especial adaptability. About 5,000 stars each month are indexed on the cards.

Aeronautics

Aerial Fleet for the Argentine Navy.—The Sociedad Sportiva Argentina has made an offer to the Ministry of War, Gen. Gregorio Velez, of an aerial fleet, to be subscribed for by the public, for which purpose 1,500,000 illustrated post cards will be issued.

The Utility of Airships in the Treatment of Tuberculosis.—Dr. Flemming, a prominent medical authority, at a meeting of the Berlin Aeronautical Association, lectured on the beneficial effects of high altitudes on tuberculosis. He pointed out that 15 minutes' exposure to the sun's rays during an airship flight at high altitude meant certain death to the tuberculosis bacilli.

Recording Births in Aeroplane.—That the regulations and rules governing aerial travel will be modeled closely upon those in use on the sea is shown in the latest set proposed by the international committee. It provides among other things, that a death or birth occurring on an aeroplane or dirigible balloon in transit, must be reported by the pilot at the first landing place.

A French Hydro-aeroplane Contest.—The Automobile Club of France has organized a concourse of hydro-aeroplanes on the coast of Brittany and around the island of Jersey. This will be one of the most interesting events of the year in the way of sport and also from a technical standpoint. It has received the patronage of the Minister of the Marine who is to send a fleet of torpedo boats to accompany the flights as well as two battleships which will be stationed in the bay of St. Malo. The British Admirality is expected to co-operate in the movement. The Automobile Club awards $10,000 in prizes, and another prize is awarded by the island of Jersey for a race from St. Malo to the island and back.

The Michelin Cup.—This year the annual aeroplane race for the Michelin Cup representing a prize of $4,000 is to be a combined speed and touring event. On a given day the pilot is to cover three separate circuits laid out in the region of Paris, with the Buc grounds as a starting point. The first circuit is Buc, Rheims, Amiens, Rouen and return, and the total distance for the three circuits is 750 miles. Gasoline can only be taken on at the starting point, and the minimum speed is 36 miles an hour, but in fact it will take a speed of 75 miles an hour to succeed in the contest This means an 11 hours' flight with the needed stops, so that the daylight period of 15 or 16 hours will be nearly approached. At all events the flights are likely to bring out some high speeds.

French Hydro-aeroplane Experiments.—During the recent maneuvers of the French fleet in the Mediterranean, the war vessel "Foudre" was fitted out so as to carry hydro-aeroplanes on board This is easier to carry out than in the case of ordinary aeroplanes, as there is now no launching platform needed to start up the flyers. On the vessel, an overhead crane takes up the flyers as they leave the hangar and drops them overboard into the water The first Nieuport monoplane of this kind piloted by Ensign Delage showed quite a success. It is of the 3-place type and carries a 100 horse-power Gnome motor. On one occasion the aeroplane was let overboard even during rough water, and it made a number of flights above the assembled fleet. One part of the fleet represented the enemy in the maneuvers and the aeroplane could observe its position and bring back a very correct report Some of the flights with one passenger on board lasted for 3 hours at a time, flying above Toulon and the harbor and along the coast. Admiral Boué de Lapeyrère and his etat-major were much impressed with the performance of the hydro-aeroplanes on this occasion.

Aviators' Sickness.—Aside from the mountain sickness, due to the rarefaction of the air and the muscular work done by climbers, and also the balloon disease with analogous symptoms but which does not appear except at very high altitudes, we now have to take account of aeroplane or aviators' sickness, whose effects have already been spoken about. These are due to the rapidity with which the maximum height is reached and the still greater speed at the descent, that is, the passage from a low-air pressure to a higher one. M. Berget, a French aeronaut, after speaking of the conditions of the atmosphere in general, also brings out some points on this question. Aeroplanes sometimes reach altitudes of 10,000 feet in an hour, and here the effects on the ear such as humming or cracking noise are about the same as in a balloon, but the effect on the respiratory organs is different. The pilot is sooner out of breath and he feels a special kind of uneasiness During the descent, the heart beats are of greater amplitude, but without accelerating. A quick descent in a sailing flight at a speed of 1,000 or 1,200 feet a minute or even more, since Morane descended at Havre from 8,000 feet height in 6 minutes, causes a feeling of a special kind, or uneasiness, accompanied with humming in the ears. Burning in the face is also felt and a severe headache, also the great tendency to sleep which has been before observed. The movements of the body are sluggish and unskilful These symptoms continue for some time after the landing, and the tension in the arteries is noticed to be higher than the normal.

The Junkers Oil Engine

A New Type of Motor on the Diesel Principle

By Joseph B. Baker

PROF H. JUNKERS, of Aachen, Germany, has developed a remarkable internal combustion engine utilizing the combustion (not explosion) of cheap, low-grade liquid fuels by the compression-ignition method of the Diesel engine, but with certain radical improvements in design which give increased efficiency and adaptation to all power purposes

Just as Watt is the father of the steam engine in its manifold forms, so in our own day Dr. Diesel is recognized as the first worker in the field of the internal combustion engine burning cheap fuel. Now comes the Junkers engine as a radical improvement in this field. Existing engines utilizing cheap fuel oils to generate power at economies unattainable in the best compound steam engines, have left much to be desired for certain stationary and marine applications, and have been inapplicable to locomotive propulsion. The need has been for an engine which could generate cheap power from low-grade oils—down to even the asphaltum oils and their residues—not only for all stationary purposes, but for propelling vessels under practical conditions and for driving locomotives

This need is now filled in the Junkers oil engine (Fig 9), in which the combustion of the fuel charge in a single cylinder urges two pistons in opposite directions. The cylinder is a simple tube, open to the atmosphere at both ends—no cylinder heads, no stuffing-boxes, no valves with mechanism The greatly superior heat efficiency, high aggregate piston speeds with low speed of each separate piston, better scavenging and cooling and lower cooling losses, and the absence of valves enable this engine to show a marked reduction of weight per horse-power—down to less than one half, in some cases one quarter—and a decided increase in efficiency when underloaded and in overload capacity. The design allows higher speeds and also a greater range of control of speed Actual engines in use include the propelling equipment for twelve ocean-going vessels now under construction, stationary engines being manufactured by prominent European companies. At present a locomotive of 2,000 horse-power, designed for a speed of 125 kilometers per hour, and weighing less than a steam locomotive, is under construction. The field open to this type of prime mover is indicated by the fact that it consumes any cheap liquid fuel, even including asphaltum crude oils.

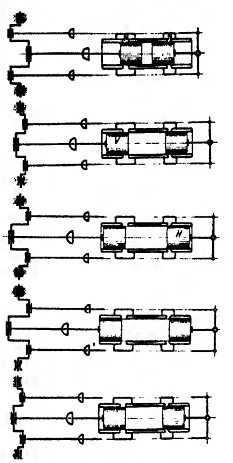
Without dwelling on technical details, the fundamental principle of operation of the Junkers oil engine may be understood by an inspection of the annexed schematic diagrams (Figs. 1 to 5) of a single cylinder engine—cylinder and pair of pistons, and the connecting rods and cranks of the engine in five successive positions throughout one revolution—in conjunction with the indicator card (Fig 6).

The arrangement of parts in the five diagrams is clear on first inspection in all but one feature. The obvious features are the open cylinder without cylinder heads, the two pistons moving alternately outward, that is away from each other, and inward or toward each other, the left-hand piston I, being connected directly to the middle one of three cranks and the right hand piston *H*, being connected to a cross head and a pair of parallel connecting rods to the two outer of these cranks 180 degrees from the middle crank, and the movement of the pistons, successively outward and inward, thus turning the main shaft The object of the ports *M* and *N* will be understood as the operation of the engine is traced through one complete revolution

The engine works on the two cycle principle. In Fig 1 the pistons are at the inner dead center, and the combustion space between them is filled with highly compressed, highly heated air as the result of the previous compression stroke In this position the oil fuel is injected in a finely dispersed condition, igniting and burning under constant pressure during the first part of the outstroke (from A to *B* on the indicator card, Fig. 6). With the supply of fuel cut off at *B*, the working stroke continues with expansion of the products of combustion from *B* to *C*, bringing the pistons to the position of Fig. 2 At this point piston I is just about to open the ring of exhaust ports *M*. As the outward motion of the pistons continues (*C* to *D* on the card) the spent gases escape at about atmospheric pressure, and the position of Fig 3 is reached, in which the exhaust ports are opening wider and piston *H* is just about to open a ring of air-ports *N*, allowing fresh air to enter and to scavenge the cylinder. These conditions are maintained until the pistons, having passed the outer dead center (Fig. 4) begin to come back on the return stroke. In Fig. 5 the inward movement of the pistons has closed both rings of the ports and the compression stroke begins on a cylinder full of cool, fresh air. The compression, *F* to A on the card, heats the confined air to such a temperature that the fuel, injected shortly before the point *A* is reached, ignites as it is sprayed into the cylinder.

The above is the complete cycle traced for a single cylinder engine of one pair of pistons. In the two-cylinder (four-piston) form, which may be built as a vertical or horizontal tandem engine with great simplicity of design, the two inner pistons move together and are linked to a single crosshead connected by a pair of rods to the two outside cranks, as shown in Fig. 7, which is a plan of the engine; the two outer pistons, which also move together, being linked by crossheads and rods to the middle crank at 180 degrees, as shown in Fig. 8, a side elevation. This construction, with two pair of connecting rods, in the horizontal and vertical planes, respectively, makes every stroke of the engine a working as well as a compression stroke.

It will be noted that the scavenging is thorough, and that both the exhaust and the former are accomplished without valves having moving parts. The compressed air for scavenging and for the fuel spray is supplied by auxiliaries driven from the connecting-rod linkage, which is extremely simple. The cylinders are simple castings, and one side of each piston is always exposed to the atmosphere and comes to rest at every outward stroke in a well-cooled region of the cylinder not touched by the products of combustion. This secures perfect cooling and lubrication. Finally, owing to the division of the total stroke between two pistons in each cylinder, a high piston speed is attained with low individual piston speeds, and a long cylinder of small diameter, most favorably adapted to thorough scavenging and to perfect combustion, may be used.



Figs. 1 to 5.—(Reading from top to bottom) diagrams showing operation of single-cylinder Junkers engine.

The Government Hunts Rats

THE United States Government is conducting a hunting expedition for rats and ground squirrels, which so far has cost it considerable money for every animal added to the kill. The expedition is in charge of the Public Health and Marine Hospital Service, which has spent $1,000,000 on the killing, and is continuing the expenditure to-day at the rate of $14,000 a month.

Rats and ground squirrels were picked out for the Government's game for the reason that they are held responsible for transmitting the bubonic plague which broke out on the Pacific coast in 1907, and so effectively has the hunting been carried on that not since 1909 has a single human being in that section of the country been affected with the disease.

In connection with its work of extermination, the Marine Hospital Service has conducted experiments in the field which tend to show that rats can live an indefinite time without water. Three of the animals were put on a diet consisting of bread, meat, and cheese, but no water, and all were alive and well 60 days after the experiment was begun. On the fifteenth day one was given an opportunity to drink, but made no attempt to do so. When kept without food, but with water one rat lived three days; and of six rats deprived of both food and water, all died within periods ranging from two to five days.

"Night Wells"

A CURIOUS form of water-hole is found in the deserts of western Australia, dry by day, but yielding an abundant supply of water by night. The flow of water is preceded by weird hissings and sounds of rushing air. The phenomenon is discussed by Dr. Malcolm Maclaren, in the *Geological Magazine*, who has, however, personally located and examined only one of these wells. He found that the water supply occurred in a long narrow trench, at the bottom of which was a thin plate of gneiss, separated by a cavity from the main rock mass beneath. Apparently the heat of the day causes this plate to expand in the form of a depression, into which the water retreats. When it cools and contracts at night it forces first air and then water back into the trench.

The head of the Celilo canal.

The Celilo Canal

By W. H. Ballou

OPENING of the Columbia River to navigation from its mouth to British Columbia is a project that has been taken up energetically and may be realized within a very few years. Steamers now bring freight to Portland from Lewiston, on the Snake River, one of the Columbia's chief tributaries, but an impassible barrier is presented at Celilo Falls and the nearby rapids, where reshipment of freight is necessary.

The most important work in opening the Columbia River to traffic is now going forward at Celilo, where a canal, on the Oregon shore of the Columbia River, 8½ miles long, with 5 locks, is being built. Two of the locks will be placed at the lower end of the canal, the total lift at this point being 70 feet. Another lock at the head of Five Mile Rapids will have a lift of 11 feet. A lock at Ten Mile Rapids, which will be used at certain stages of water only, has a lift of 5 feet, while the fifth lock, at the upper end of the canal, with a maximum lift of 9 feet, will also be required at certain stages of the river.

Rock excavation for the tandem locks.

The project now under way was authorized by Congress by an act approved in 1905. The cost of the work will be almost $5,000,000. The work involves the excavation of 1,300,000 cubic yards of rock, 750,000 cubic yards of sand, 700,000 cubic yards of earth, the construction of 200,000 cubic yards of concrete and 5,000 cubic yards of rubble masonry.

The Rivers and Harbors Act of June, 1910, appropriated $600,000 for continuing construction on the canal with a view to completing it in 6 years. The new work includes the excavation of about 5½ miles and, in addition, the placing of a concrete lining in sections excavated under former contracts, as well as the designing and installation of lock gates and machinery. Maj. Jay J. Morrow, Corps of Engineers, U. S. A., in charge of the first Portland district, decided, at the time of the last appropriation, that it would be advantageous to supervise the work directly rather than let contracts, as had been done previously. This plan was approved by the Chief of Engineers, U. S. A., and First Lieut Henry H. Roberts, Corps of Engineers, U. S. A., was at once placed in local charge of the entire project, involving the completion of contracts already in effect, and the completion of work by hired labor. The organization of affairs required some little time, but construction work was gotten under way in October, 1910, and it has proceeded steadily ever since.

In prosecuting the work, careful tests have been conducted by the officers in charge, to determine the qualities making for the best results, and materials have been placed in the work strictly on their merits. An odd feature is the maintenance of a sand-crusher plant, whereby stone rejected from the rock crushers, which crush rocks for concrete, are reduced to sand. This is somewhat singular from the fact that there are sand dunes nearby where this material could be secured; but it is found that by manufacturing it, its cost is not only reduced, but the tests show it to give a greater tensile strength to concrete than any natural sand available for the work.

The Columbia River Valley is one vast granary, and in autumn great piles of wheat sacks are placed at railroad stations and river landings awaiting shipment to the Portland market. Great economies in transportation will be effected if this great tonnage of wheat can be placed on board steamers and floated down stream all the way to Portland. This is ideal transportation, effected at the least possible cost. At present a portage railroad at Celilo transports freight, both up and down the river, past the places in the stream impossible of navigation. This additional hauling of freight is expensive and causes delay.

The canal work is expected to be finished not later than 1916, and when this is accomplished the wheat, hay, fruit, and much of the livestock, which comprise the chief staple products of the Inland Empire, will find an ideal outlet to Portland, and thence by water or by rail to the markets of the world.

Instrumental Observation of the Sun's Heat

By the Paris Correspondent of the Scientific American

THE instrument which is being used by Dr J. Dupaigne in France for observing the heat of the sun presents several interesting features, one of these being a thermometer made with a hollow conical bulb. The aim is to have the sun's rays fall upon a cell or absorbing chamber so that the effect of the rays will be thus concentrated. An ordinary thermometer, even though blackened, will always reflect a good part of the rays, and these will be lost. Dr Dupaigne had the idea of making a combined cell and thermometer. Instead of using a solid bulb, he makes a double-walled one in such a way that the mercury is spread around in a thin layer just as it would appear if put between a double funnel, and the stem of the funnel extends as a tube so as to form the thermometer. When the sun's rays fall into this conical-shaped cavity (A in the diagram, Fig. 1), which is blackened so as to absorb them, they are not reflected again, as they are caught by the sides of the narrow funnel, which has a 30 degree angle. This principle is due to M. Féry, but Dupaigne here applies it to a thermometer for the first time. This is placed inside a Dewar double-walled and silvered globe so that the bulb cavity is turned toward the sun's rays and the long stem of the thermometer extends to the rear. The globe acts so as to prevent loss of heat. In this way the user is able to estimate the heat of the sun under the best conditions. It is the quantity of heat and not the temperature which is measured, and such an instrument is a special form of calorimeter, here shown in Fig. 2 and named actinometer.

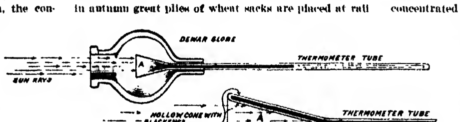

Fig. 1.—Diagrammatic illustration of the method of absorbing the sun's rays, so caught by the sides of the blackened hollow cone A that they cannot be reflected and lost. The lower sketch is an enlarged view of the cone or funnel.

Fig. 2.—The actinometer in position to receive the direct rays of the sun.

Night Letters in Italy

A NIGHT letter service similar to that which has become so popular in the United States and Great Britain has just been adopted by the telegraph system of Italy (a state institution). According to a law recently passed this service is, for the present, applicable to a list of designated places. A uniform charge has been adopted of 2 centesimi (about $0.004) a word, with a minimum charge of 60 centesimi ($0.116).

Burning Up Bad Roads to Make Good Ones

By C. H. Claudy

GOOD roads present many different problems in different localities, according to the building material at hand and the character of the soil. Perhaps no more difficult conditions for the making of good roads exist than in the lowlands of the Mississippi Valley, where centuries of swamps and tons of decayed vegetable matter have incorporated in the "gumbo" or "buckshot" clays of that region a plasticity and mud-making ability which produce the worst "roads" in the world.

During certain seasons of the year, these so-called "roads" are absolutely impassible, vehicles sinking to the hubs and horses getting so mired that they must either be shot or dragged out with ropes, often with broken legs to pay for their drivers' temerity.

To make a good road out of this "gumbo" is a problem, the importation of sand for a sand-clay mixture is too expensive, and there is not enough rock in these localities to make a hitching stone, let alone a macadam road. But a solution of the problem has been found in the "burned clay" road, in which the "gumbo" is so changed in character by firing as to present a fairly hard and mudless surface, even after a heavy rain.

The "gumbo" clay is black from the large percentage of organic matter it contains, and from the same reason is peculiarly sticky and plastic. But after having been baked, it forms a clinker, which, while not rock-like in its hardness, shows no tendency to form mud when mixed with water. This surprising fact is made use of by the farmers living in the "gumbo" regions, to make the "burned clay" road. Luckily the districts of "gumbo" are heavily wooded, and fuel is cheap and does not need to be hauled. The process of making a "burned clay" road is as simple as it is novel. The width of the road is determined, and it is ditched on either side. Next the surface is plowed up as deeply as possible, and even four mules make a hard job of dragging one plow through the sticky clay. The plowed up clay is then thrown into furrows across the road, making ridges about four feet apart. Cord wood is laid closely across the tops of these ridges, making a wooden floor above the clay, the furrows and ridges forming flues. Fire wood is piled irregularly on this wooden floor, with masses of clay filling in the open spaces. A second course of cord wood is laid on top of this mixture of wood and lumps of clay, and all openings filled with kindling and light wood. The whole is then covered with a clay blanket—usually taken from the ditches on either side—to a depth of a foot, and tamped and rounded off so that the heat may remain in the mass as long as possible. Where coal slack is available, it is often substituted for wood. The point is to get heat regardless of what fuel is used.

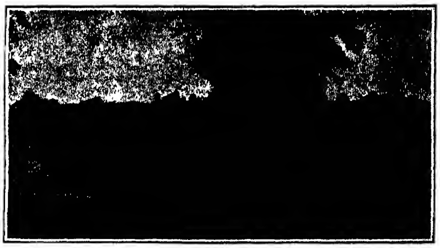
When completed, the flues are fired so that they will get the draft down wind. The workmen pay careful attention to the burning, and when any part of the fire seems to slack up, reinforce that flue with light kindling, so that an even burning is maintained throughout the mass.

When the wood is all burned—the organic matter in the clay aiding the combustion and in giving off heat—and the mass sufficiently cool, it is found that all the clay on the first floor, all the clay on top, and even the ridges of clay between the furrows, as well as underneath the lowest fire, has been thoroughly clinkered.

To make the loose mass into a road, nothing is needed but grading with plow or scraper to make a high crown in the center and a final compacting by rolling.

The result is a hard surface road which refuses to get muddy, which wears well, costs next to nothing to repair, and which provides a safe bridge through "gumbo" country. On either side of the roads all winter long, no carriage could roll—on top of the six to eight inches dressing of burned gumbo clinker, heavy wagons travel without difficulty.

The cost of such a road varies between $1,000 and $1,500 a mile, a very small price to pay for a good road, and particularly in a district where, until the coming of the "burned clay," transportation except by railway was, in the winter time, an absolute impossibility.



Burned clay properly spread ready for leveling by rolling.

Salving the Steamer "Jose"

THE fruit steamer, "Jose," lay at her dock in the East River, New York, taking on a cargo of case oil and gasoline for Central American ports when a serious fire broke out. The vessel was towed out into the stream to prevent the fire from spreading to the dock and other shipping. The fireboats pumped such a deluge of water into the vessel that it sank off shore in thirty-eight feet of water. This happened on the 13th of March of this year, and it was not until the last of July that the work of raising the vessel, pumping it out, and delivering it to the owners could be completed. The wreck could not have been sunk in a more unfavorable position. The bottom on which it lay was covered with boulders which, at that point, formed a pocket about eight feet deep. This meant that the vessel would have to be raised at least ten feet before it could be towed to a position more favorable for the wrecking operations. The "Jose" lay right in the path of shipping, and at a point where the tides were so strong that work was actually limited to the period of slack water at high and low tides.

The task of raising the steamship was undertaken by the Merritt & Chapman Derrick and Wrecking Company, and the method they employed is pictured in our front page illustration. While the method is not a new one, we believe that our readers would be interested in learning just how such work is done.

The wrecking outfit consisted of six pontoons, three on each side of the sunken vessel, and two barges, the latter furnishing the steam for the pumps on the pontoons. The pontoons were provided with chain wells of the form shown, partly broken away in one of the detail views. The wells were of flat triangular form, flaring out at the bottom, which was open to the water, so as to allow for the sweep of the chain. There were four such wells to each pontoon, and the chains passed from the pontoons on one side of the vessel under the hull and to the pontoons on the other side. Beside each chain well, there was a mast which was provided with fall and tackle by which the slack of the chain was taken up. The chains as they emerged from the wells passed through planks fulcrumed at one end, and arranged to be lifted by hydraulic jacks at the other end. The chains, after being drawn up taut by the tackle, were fastened to the planks by means of toggles, or U-shaped pins, fitted under the chain links, and then hydraulic jacks were operated to secure a uniform tension.

As the pull of the wreck on the chains would tend to cause the barges to come together, they were kept at the proper distance apart by means of beams known as "spreaders." There were also top timbers that ran across the wreck from pontoon to pontoon, and were fastened to the pontoons by means of chains that passed around their hulls, as shown clearly in one of the detail drawings. These served to keep the pontoons on an even keel.

Had the "Jose" rested on a soft bottom it would have been a simple matter to pass the chains under it. They could have been lowered under the bow and then worked back and forth until they reached the desired position. But as the wreck rested on boulders, such a course was impossible. It was necessary to get the chains under at fixed points corresponding to the position of the chain wells on the pontoons, and this necessitated in many cases the blasting of a channel under the wreck, through which a small chain could at first be passed, and then be used to haul a heavier chain through. The divers could not work at the bottom when the tide was running, as it was strong enough to sweep them off their feet. In the short intervals of slack water, but little could be accomplished, and so the work dragged on through several months. There were a number of delays, due to snapping of the chains when the pontoons were rocked by swells. As the wreck lay in the path of navigation there was much apprehension whenever any large vessel passed by. However, the regular sound steamers very considerately reduced their speed when passing the wreck so as to prevent any accidents. The chains were also crushed by contact with the boulders as the vessel was moved over them.

Although the task of passing the chains

A Suggestion for Typewriter Makers

To the Editor of the SCIENTIFIC AMERICAN:

I would like to suggest that the manufacturers of typewriters adopt a keyboard that would be best adapted for the touch method of operating and all of them manufacture the same.

This would standardize the typewriter like musical instruments, most notably the piano and would be of convenience to people in obvious ways.

Santa Ana, Cal. B. T. BAKER.

The First Parachute Drop from an Aeroplane

To the Editor of the SCIENTIFIC AMERICAN:

We beg to call your attention to an error in your issue of July 6th, on page three, under heading of "Aeronautics," in which you state that the first parachute drop from a flying machine was made by Law. For your information we would like to state that the first successful drop from an aeroplane was made by Bert Berry in a Benoist biplane, driven by Tony Jannus, at Jefferson Barracks, Mo., February 29th, 1912. You can find an account of this in any of the New York papers the day following, as this attracted universal attention, and was taken up by many of the foreign papers, the *London Graphic* carrying photographs on the complete front page. We are inclosing herewith a description of this taken from *Aero* of March 9th. THE BENOIST AIRCRAFT COMPANY.

St. Louis, Mo.

Determination or Free Will?

To the Editor of the SCIENTIFIC AMERICAN.

In the issue of August 17th, 1912 a Mr. Paul R. Birge makes this rather startling, positive and dogmatic statement: "From the deterministic, the only thoroughly scientific standpoint, there is no line separating responsible wickedness from acts against the public peace which have their origins in perversities, etc."

He here out-Haeckels Haeckel in making a statement, which, to the hasty reader, would pass for a scientific truth grounded upon fact while in truth he has not proved the statement. What is science? The following is Huxley's definition (see "Value of Natural History Sciences," Lay Sermons, page 73): "Science is nothing but trained and organized common sense."

Prof. Haeckel says in brief on page 6 of "The Riddle of the Universe:" "All purely scientific investigations consists of: firstly, experience; secondly, inference."

Is determination proved from experience? It is not. In fact all experience and common sense is for the freedom of the will. We make a practical application of it every day. As Doctor Johnson says, "Sir, we know our will is free and there's an end on't; all theory is against the freedom of the will; all experience for it."

As determination cannot be proved from experience, according to the above definitions of science, it is therefore not a thoroughly scientific standpoint. Theories that are not grounded upon the facts of experience have no right to be called scientific, still less to be called thoroughly scientific and the only scientific standpoint.

I wonder which is the more scientific, determinism or Free Will?

Washington, D. C. C. H. K.

Bow-on Collisions

To the Editor of the SCIENTIFIC AMERICAN:

In your issue of August 17th, under head of "Danger of Bow-on Collision," your Californian correspondent seems to have entirely overlooked the fact that the strength of the plates which compose the hull of an ocean steamship as compared with the total weight of the ship are an almost negligible quantity.

He says "when the forward motion of a ship is *suddenly stopped* nothing whatever could hold the boilers and engines from breaking loose and going forward and smashing the bulkheads and probably the bottom," and then he pictures the horrible results from the breaking of the steam pipes.

Now anyone with the least amount of practical knowledge of the strength of material knows that such conditions are impossible.

A big steamship, as a whole, cannot be instantly stopped because the force of any blow that may strike the outside of the hull will be taken up by the successive crumpling of the plates, so that in a very large ship scarcely any jar would be felt in the middle of the ship, as was, in fact, noted by the passengers on the "Titanic."

Such results as your correspondent imagines could only occur if the ship were built of so great strength as to be virtually one solid body, but as such a ship could not float at all, the conditions are impossible.

The reason why no notice was taken by any newspaper of the letter which Mr. Fraser sent to the Investigating Committee is self evident, for it seems to be a waste of space for any paper to publish so absurd a theory.

Gloucester, Mass. REUBEN BROOKS.

The "Akron" Accident

To the Editor of the SCIENTIFIC AMERICAN:

We have noticed with interest the various reports which have appeared in the SCIENTIFIC AMERICAN, as an attempt to explain the explosion of the dirigible balloon, "Akron," at Atlantic City, on July 2nd. We find it necessary to correct a few points on which you have apparently been misinformed. It is true, to a certain extent, that the "Akron" showed no speed lines. It was not built for them. It was built according to the specifications which we received, and corresponds exactly to them.

The rudder was not small, although perhaps not quite properly balanced, and required too many turns of the wheel to move it.

The "Akron" was equipped with aeroplane surfaces of about sufficient size to give a reaction of about 1,000 pounds either up or down. Such a reaction would be sufficient. There was only one pair of orientable propellers, driven by the central power plant. There were U-tube pressure gages from all the ballonets and from the gas compartment.

The hydrogen used was exceedingly pure, and tests showed that the fabric had suffered practically no deterioration from this or any other cause.

You may be interested to know our views in the matter.

There was no representative of the Goodyear Tire & Rubber Company in Atlantic City to witness the accident, and, consequently, we must base our conclusions on the various and some times conflicting reports of those who were eye witnesses, and upon the investigations which we have made as thoroughly as possible of the remnants of the wreck.

The wreckage was raised from the water at considerable expense, and its condition carefully noted Sample pieces of fabric were tested out, and all possible tests made that could in any way throw any light on the cause of the accident, and probable reason for it.

We regret that our statement, from the very nature of things, cannot be as explicit and satisfactory as we would like to have it. However, we will give it to you for what it is worth, and from it you can draw your own conclusions. We have made it out in the form of a general discussion of all the theories of the possible cause of the accident. It is hard to tell which one is the most plausible.

In thinking of the dirigible balloon "Akron," kindly remember that the gas bag only was constructed by the Goodyear Tire & Rubber Company, and that, according to the general specifications and suggestions of Mr. Vaniman. The car and the entire work of assembling was carried on at Atlantic City under the direct supervision and direction of Mr Vaniman. We believe strongly in the future of the dirigible, considering it only a matter of time before its development in this country will equal and surpass its development in Europe and other foreign countries. We believe that this accident contributed a great deal to the science of the manufacture and operation of the dirigible balloons.

We are ready to construct dirigibles of any type, and will welcome anything that you can do to assist in bringing the dirigible to its successful completion in this country.

Any and all of this letter is for publication if you so desire, for we are willing and in fact wish everybody to know the true facts of the case. We are glad to furnish any and all information which we can, which will in any way throw any light on this unfortunate accident, and aid the science of aeronautics.

Unfortunately a complete examination of the gas bag was impossible, as a large part of it had been cut up and carried away as souvenirs, before it could be protected. Our complete report is as follows:

A large number of witnesses were investigated, whose accounts vary greatly as to detail, but the following summary covers the points on which reliable eye witnesses agree and which we have determined from our investigations.

The balloon started directly away from the hangar, and holding its course, proceeded to a point over Brigantine Beach, then made two wide circles, and was making the third when the accident occurred. The ship was rising during the whole time that it was in the air, and had attained an elevation of about 2,500 feet.

Shortly before the bag collapsed the bow of the ship seemed to be pointed downward and the orientable propellers running, apparently in an effort to bring the ship down to a lower level. Accounts vary as to the exact method of collapse of the bag but the general opinion is, that the rent in the bag occurred near the stern; the ship was almost on an even keel, and poised a moment in that position, then the stern sank and she plunged downward; when part way down the greater portion of the bag tore loose from the car; the car shot downward stern first in a nearly vertical position until almost down to the water, when it swung around, partially righting itself, then struck stern first in nearly its normal position. The portion of the gas bag which had been torn loose, dropped into the water a short distance from the wreck, and floated up the channel with the tide.

There have been several theories advanced as to the cause of the accident

(1) *Fire or explosions* —There was no evidence confirming this theory, the tanks, while battered up and more or less broken to pieces, showed no signs of having been ripped open by an internal explosion All the motors were recovered but the small one and the cylinders found to be intact. Some of the bodies were burned, but the doctor who examined Calvin Vaniman stated that those burns were probably made by hot liquid of some kind (presumably hot water from the radiators) and not by hot iron, burning gasoline, or by flame

A violent explosion of gas would have been impossible. Recent tests of the gas showed it to be over 80 per cent pure hydrogen, although the balloon had been inflated nearly four months. There was no signs of fire discovered on any part of the balloon except one small spot on the fabric, which had evidently come in contact with a hot pipe. A few reports of smoke and flame having been seen are current, but most witnesses, particularly those familiar with the operation of gasoline engines, say that the smoke was only the exhaust from the engine, and that there was no flame.

(2) *Rupture of gas bag due to internal pressure* —There are many stories current as to the gas bag being made of under-strength fabric, or that it rotted from exposure, or from impurities in the gas The facts are these

Mr. Vaniman specified in his design a maximum pressure corresponding to 1 inch of water. The balloon was actually built to stand an ultimate pressure of 8 inches, thus giving a safety factor of 7, which considerably exceeds the usual figure. But there was reason for this excess strength It was to be an experimental machine of rather a novel design, and the first ever made in this country. Likewise, Mr Vaniman, although a great inventor and genius in his way, had not had the long practical experience with dirigibles which is given the European pilots, and which insures their doing the right thing at the right time As to the fabric being rotted by the gas, or otherwise, it is sufficient to say that samples cut from different parts of the bag after the accident, showed no material deterioration in strength All seams were triple reinforced and showed far over the 100 per cent efficiency as recorded by the numerous tests. Although, on account of the souvenir hunters it was impossible to tell where the bag had first broken, it is manifest that no seams (so far as observed) had been even strained.

In spite of the extra strength, the balloon could very easily have been burst by letting the pressure go up to an excessive amount It would take a fabric 50 times as strong to resist all the expansion likely to occur from the sun's rays and it would be impossible to resist that due to increasing altitude. There is some slight evidence which seems to point in this direction. It was morning, the sun was getting hot and the balloon was rising at the time of the accident. Only the two rear engines were running There were scalds on Mr. Vaniman's body which would indicate that something had called him to the rear of the car, away from the pilot's bridge where the pressure gages were located He had a large automatic safety valve of French manufacture, which should have been ample to take care of just such an emergency, but we found on examination that he had provided it with extra springs since the first flight, which did not allow it to open fully. On the other hand the bottom of the bag was made purposely weaker than the top so that if it did burst it would in all probability retain enough gas to let the machine down in safety.

(3) *Breakage of the suspension ropes* —This theory has not to our knowledge been advanced before, but it would well explain all the observed facts and has strong evidence to recommend it The size rope used for supporting the car gave a nominal safety factor of only about three (3), and they had been tightened up much beyond their proper allowance We have it from two of the mechanics that these ropes had been breaking frequently when simply standing in the shed. If two or more of them happened to break at once, all the others would speedily follow suit, thus throwing all the strain on the bottom fabric, tearing it open and ripping the whole bag from the car.

Propeller breakage —This also seems a plausible theory. We regard it as practically impossible that a propeller could have broken from centrifugal force alone. They were of wood, run at a slow speed, and were specially designed for the work by a reputable French concern. If, however, any part near the one broke, a suspension rope for instance, a blade striking it, would be easily broken off and might fly into the gas bag in such a way as to cause a fatal rupture

While we deplore the fact that it was impossible to determine the exact cause of the accident, one may well take satisfaction in the fact that all the accidents outlined above are entirely preventable.

In the meantime, we cannot appreciate too much the work of those who went to their death for the cause that is yet new, and which, like everything new, demands more than its share of money and lives

Curious Megalithic Monuments of France

By Jacques Boyer

WE will not commence this article with a minute study of the 4,458 dolmens and roofed alleys which the French Commission of Megalithic Monuments has recently catalogued, but we will simply, in the first place, glance at these imposing relics of prehistoric times, that are doubtless contemporary with the menhirs, colonnades and cromlechs, which we shall speak of later.

According to the definition given by Bonstetten and generally adopted by archeologists, a dolmen is a monument of stone, bare or covered with earth, and of dimensions sufficient to contain several tombs. It is constructed of a variable number of rough flat stones supported in a horizontal position by a variable number of stone pillars. The number of pillars may be only two, as in the dolmen known as the Merchants' Table at Locmariaquer in Morbihan (Fig. 5); three, as in the Pierre-Levée at Brantôme in the department of Dordogne (Fig. 6); four as in the Urbe dolmen in Creuse (Fig. 3), and the Roche-aux-Loups at Beaumont in Dordogne (Fig. 7), or a still larger number.

If the dolmen contains many pillars supporting several entablatures, it is called a roofed alley.

An exceedingly fine specimen of this class, the Roche-aux-Fées (Fairies's Rock), is still seen standing near Rétiers in the Department of Ile-et-Vilaine.

The megalithic monuments are not evenly distributed throughout France. They are rare in the east and southeast except in the departments of the Aube and the Alpes-Maritimes, according to the statement of Joseph Déchelette in his "Pre-historic Archeology" (1908). They are found most abundantly in a

Fig. 4.—Menhirs at Lampary.

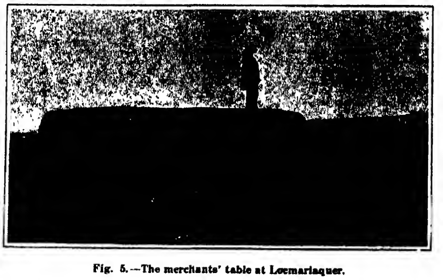

Fig. 5.—The merchants' table at Locmariaquer.

zone included between the Breton Coast of the English Channel and the Mediterranean shores of the departments of Gard and Hérault. Two very compact groups may be distinguished: the southern group, including the five departments of Ardèche, Aveyron, Gard, Lot and Lozère; and the western or Breton group, which is most densely aggregated in Finistère and Morbihan.

The attentive study of the dolmens and roofed alleys shows that their builders placed the large entablature stones with their plane faces downward or inward, paved the floor below with smaller flat stones and, in general, filled the interstices with still smaller stones. Some of the pillars and roof stones are so huge that it seems almost impossible that they could have been transported and assembled in the infancy of civilization with the aid of rudimentary tools, especially as some of these stones have evidently been transported to considerable distances. For example, a stone weighing 40 tons, found at Perotte has been moved 19 miles and one at Moulins 22 miles.

The method employed by these prehistoric builders are entirely unknown to us; but experience has demonstrated the possibility of transporting and erecting very heavy masses without the aid of complex machinery or even of ropes. The stone can be raised by means of a series of levers and supported by placing earth beneath it. After the block has been raised to a certain height it can be allowed to glide down a sloping bank of earth plastered with clay, and by repeating these operations, the stone can be transported to an indefinite distance. Possibly the cave dwellers made use of ropes and of round logs, rolling on a path paved with smaller logs or planks. Whatever method was employed, the construction of the megalithic monuments required a spirit of order and discipline.

Smoke, the Destroyer

By R. C. Benner, Ph.D., University of Pittsburgh

According to the smoke inspector of Chicago, the black fumes belched by the chimneys of his city cause an annual loss of fifty million dollars in ruined merchandise. Since one third of the American population lives in cities, the United States Geological Survey estimates, on the basis of this smoke inspector's figures, that the total loss caused by soot reaches a dizzy total of six hundred million dollars. Here is indeed a problem for the scientist. That he has not neglected his opportunity is evidenced by the following article, which, written by the chemist in charge of the University of Pittsburgh's smoke investigation, shows exactly to what the destructive action of smoke is due.—EDITOR

IT may seem surprising that an architect should specially interest himself in the purification of the air, but the problems confronting him in the designing of buildings to be erected in a smoky town are so manifold as to make a clean atmosphere a matter of moment. For architecture does not depend upon a knowledge of materials alone, nor upon designs of beauty alone, but is very dependent upon the atmosphere, and when smoke pollution is taken into account one has much to contend with.

Soot possesses the properties inherent in itself for making the worst possible kind of dirt.

1. Finely divided carbon forms the basis of our best black paints. It is opaque and has a large covering power, i. e., a little will make a large surface dirty.

2. It contains tar, which, as well as being black and corrosive, causes the soot to stick to any material with which it comes in contact.

3. Finely divided carbon has a great absorbing power, absorbing large amounts of the sulphur acids, more especially sulphurous and sulphuric, with minor amounts of hydrogen sulphide.

No wonder that our houses look grimy and miserable and that the use of skylights in many places is made impossible, while in others it is necessary so to arrange them that they may be readily cleaned. Otherwise they would soon become useless because of the accumulation of soot.

Again, changes in design so as to make a different arrangement of drain pipes, etc., are, at times, necessary in order to prevent the splashing of rainwater containing soot upon the building.

In a smoky city, too, much more glazed tile and vitrified brick is used for the outside of buildings, as it makes the cleaning a comparatively simple matter, washing alone being necessary. Building stones, such as limestone, marbles or sandstones, with calcareous binding material are rapidly disintegrated by the acid in the soot and the air. Therefore, materials such as granite, sandstone (with a silicious binding) brick, etc., which are not attacked by the sulphurous and sulphuric acids in the soot, should be utilized. But, unfortunately, that stone which is most easily affected, disintegrated by the atmospheric acid and decolorized by soot, is the one which it is easiest to work into the desired shape for building purposes. Granite and similar stones, which are practically unattacked by acid and impervious to moisture, consequently offering little chance for the soot to lodge and readily cleaned, are extremely expensive because of the difficulty in working. Thus the architect finds himself confronted with monetary considerations.

In Glasgow, several years ago, the subject was widely discussed and various remedies were advocated, i. e.: Painting the stone with paraffine, similar to the treatment given the Obelisk in Central Park, New York, and covering with solutions of soap and alum, silicate of soda, carbonate of baryta, etc, and also patented preparations. These are all more or less effective and tend to reduce the evil effects of the acid and soot to a minimum by closing the pores of the stone. Sand blast is used for cleaning in some places, but this abrades the surface, leaving it rougher than before.

Hydrochloric acid is utilized for washing down stone walls, but it must be used with care, as discoloration is likely to follow. Cleaning the stone is at least but a temporary expedient and represents a periodic tax on the owner. The logical thing is to make cleaning unnecessary by water-proofing the stone and doing away with the smoke.

The sulphuric acid in the air and occluded in the soot acts on calcium carbonate (the principle constituent of stones most readily corroded by the acid in the soot), and forms calcium sulphate (gypsum), which is more readily soluble in water than the calcium carbonate but, at the same time, causes the stone to undergo a physical change, making it swell and become porous and friable and easily disintegrated, also roughening polished surfaces, thus making them more susceptible to attack by acid and moisture and also easily affected by weather.

Dr. Angus Smith has found mortar to contain 28.33 per cent of sulphuric acid, equivalent to 48.16 per cent $CaSO_4$ caused from the action of the sulphuric acid in the air on the calcium carbonate. Limestone and marbles have been found to contain 0.52 to 3.85 per cent $CaSO_4$, and because of the comparative ease with which this substance is soluble in water, the surface is readily eroded. The effect of the sulphuric acid absorbed in soot is rather marked on most metals and greater than the action of a like amount of acid in the rainwater or air. It would seem from observations taken in Pittsburgh that soot containing acid adheres to the metal by means of its tar content and forms an electrolytic couple, thus making corrosion much more rapid. In the case of iron and aluminum, the oxide (or basic sulphate) is produced, at least in part, from the sulphate, and the acid is used over and over again.

Lower story of Keenan Building after it had been washed down. This story is cleaned twice a year.

To experimentally verify these observations, duplicate sets of various metals were fastened to two boards. One set was protected from the soot in the air by means of cheese cloth, yet still exposed to the air and the rain. The other set was left unprotected from the soot and it shows a much greater amount of corrosion.

The following figures obtained by Messrs. W. B. Worthington and A. Rattray, show the accelerating effect of the acids in the air. Quoting from Cohen, "A number of rails were placed in suitable positions by the side of the line, and weighed at intervals and the loss of weight recorded. The rails were of the ordinary railway section weighing 86 pounds per yard." The annual loss of weight from corrosion was as follows:

	Loss in weight in pounds per average year	No. of years of observations
1. In the center of the town	1.04	17
2. In adjoining place in smoky tunnel	1.48	13
3. In a wet place in same tunnel	1.71	8
4. On the seacoast among sand hills	0.18	17

The question of exterior and interior decoration is one affected as much by the amount of smoke in the air as by the tastes of the owners of the building. Interior

The Heavens in September

Indications of the Sun's Motion Through Space at 12 Miles per Second

By Henry Norris Russell, Ph.D.

WE considered last month some of the conclusions which might be drawn from a study of the motions of the stars in Scorpius and Sagittarius; but we were far from exhausting this topic.

The diagram, showing the amount and direction in which each star will move in the next hundred thousand years is reprinted here, and, for comparison, a second is given exactly similar in nature, but exhibiting a portion of the northern heavens (now visible in the evening sky), in which the constellations Lyra, Hercules and Corona Borealis may at once be recognized.

Each illustration shows all the stars in the given region which are brighter than the fourth magnitude, with the addition of a few slightly fainter ones to mark certain familiar constellation figures

It needs only a glance to see that there are very marked differences in the way in which the stars in these two regions of the sky are moving. In the vicinity of Scorpius almost all the stars are moving southward and westward (that is, downward and toward the right on our diagram) This applies not only to the stars of the moving cluster which we described last month (which are all going in the same direction and at the same rate), but to the remaining stars, which though moving in different directions and at different rates show the tendency to move downward in all but two cases out of sixteen, and a distinct, though less overwhelming tendency toward the right.

In the region of Hercules the situation is quite different Hardly any two stars are moving in the same direction or at the same rate, and motions to the right or to the left, up or down, occur with an entire lack of system, while four stars are moving so very slowly that even in 100 000 years they will not have changed their position by an amount great enough to show on the diagram, so that they appear simply as dots with no arrows attached to them

In the first region we have some approach to order in the stellar motions, in the second we find chaos It may seem at first sight surprising that it is the order, and not the chaos which demands explanation, but we must remember that the stars which seem to us to be neighbors in the sky, and to form a definite configuration have usually no real connection at all; some are many times as far away from us as others, and they only seem near together because they are nearly in line with one another from our particular point of view We need not, therefore, expect to find the stars of a given constellation moving in the same direction, much less at the same rate, and, unless we can show some definite reason to the contrary, we may expect to find as many going northward as southward, and eastward as westward

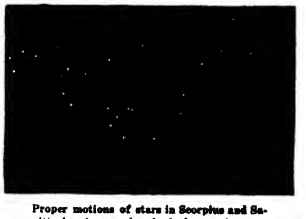
This is just what actually happens in the region of Hercules, and we may, therefore, rest content to ascribe what we observe there to mere chance

Something more than chance, however, determines the apparent *rate* of the stars' proper motion. Of two stars, each of which is really moving (at right angles to our line of sight), at the same number of miles per second, the nearer one will seem to move the faster, in direct proportion to its nearness It is, therefore, likely that the stars which have the largest proper motions are the nearest to our system But this is by no means an infallible test, for a star whose actual motion, in miles per second, is very rapid, will seem to move fast, even if at a considerable distance In spite of such exceptions, it is undoubtedly safe to assume that the stars whose apparent motion is rapid are, on the average, much nearer than those which seem to move slowly

These principles are well illustrated by the four fastest moving stars shown on the Hercules diagram They have all been repeatedly observed for parallax, and the results show that they are all relatively near our system

Zeta Herculis (shown in the upper right-hand part of the figure) is the nearest, its distance being about 23 light-years Next come μ Herculis and Vega (the two rapidly moving stars in the left-hand half of the diagram), whose distances are 31 and 35 light-years, according to the latest observations. The star of largest proper motion of all in the region, γ Serpentis,

Proper motions of stars in Hercules, Corona and Lyra in one hundred thousand years.



Proper motions of stars in Scorpius and Sagittarius in one hundred thousand years.

appears to be farther off, about 60 light-years (according to the mean of three measures of its parallax, which do not agree as well as in most cases). Its actual rate of motion must be much more rapid than that of the other stars. But why do the stars in Sagittarius behave so different? It may still be true that those which seem to move fast are, on the average, nearer to us than the others; but this does not explain the general southerly drift of all the stars in the region. If this peculiarity was confined to the constellation we might be content to say that the stars in this particular part of the heavens had a peculiar tendency of their own; but much the same thing, though not to quite so marked a degree, is found in other parts of the sky. There is a distant preference, among the motions of the stars for a certain quarter, and an avoidance of the opposite quarter. The favored directions run by no means at random. They all point away from the region of Hercules and Lyra, and, toward that of Canis Major.

Our Sun itself is the seat of the motion, and is steadily progressing through space, like the other stars, carrying all its attendant planets with it. The apparent drift of the heavens is the reflection, if we may so speak, of this motion of our system toward Hercules.

In either of these regions the influence of the solar motion changes only our distance from the stars, without influence upon their apparent motion across the sky, and we get a chaos of proper motions with no marked preferences. But when we look out nearby at right angles to the motion of our system, as is the case in Sagittarius, the apparent drift is at a maximum, and only those few stars which are going the same way as the Sun, but faster, appear to move opposite to the general run of the stars. It need hardly be added that this hypothesis of the Sun's motion has been fully tested, and the proof clinched by spectroscopic observations. The average rate at which we are growing nearer to Hercules, and farther from Canis Major, is twelve miles per second, which must obviously be the rate of the Sun's motion in space.

The Heavens.

The regions of the sky of which we have spoken are both visible in the early evening, though by our hour of observation a part of the southern one has set. We may still find Sagittarius near the southwestern horizon, and, passing northward over Ophiuchus, recognize Corona, Hercules, and Lyra a little north of west, the last high up toward the zenith. Cygnus is still higher, practically overhead. The Great Bear is low on the northwestern and northern horizon, with Draco and Ursa Minor above. Cassiopeia and Cepheus are above the pole, and below the former, in the northeast, are Perseus and Auriga. Taurus is rising, and Cetus occupies the southeastern sky. Above these are Aries and Pisces, then Andromeda and Pegasus. Aquarius and Capricornus occupy a wide dull region in the south. Lower down is the bright star, Fomalhaut, in the Southern Fish, and still lower the constellation of the Crane well visible only in more southern latitudes.

The Planets.

Mercury is morning star all through the month, and is well observable about the time of his greatest elongation on the 7th, when he rises only a little after 4 A. M. He is in Leo, and passes about five minutes of an hour north of the bright star Regulus on the morning of the 10th. This will be an interesting conjunction. The planet is much the brighter of the two, exceeding the star about fivefold.

Venus is evening star in Virgo, and may perhaps be seen low in the twilight in the latter part of the month, when she sets about 6:40 P. M. Mars is also an evening star, theoretically, but is too near the Sun to be observable.

Jupiter is evening star, setting about 9:30 P. M. in the middle of the month.

Saturn is in Taurus, and rises about the same time that Jupiter sets.

Uranus is in Capricornus, and comes to the meridian at 8:30 P. M. on the middle of September. Neptune is in Gemini, observable only in the morning hours.

The Moon is in her last quarter at 8 A. M. on the 4th, new at 11 P. M. on the 10th, in her first quarter at 3 A. M. on the 18th, and full at 7 A. M. on the 26th. She is nearest us on the 9th, and farthest away on the 21st.

At 5 A. M. on the 23d the Sun crosses the equator and enters the "sign" of Libra, though not the constellation, since the precession of the equinoxes has carried the two out of agreement since classic times. But in any event, we may say with precision that this is the moment of the autumnal equinox.

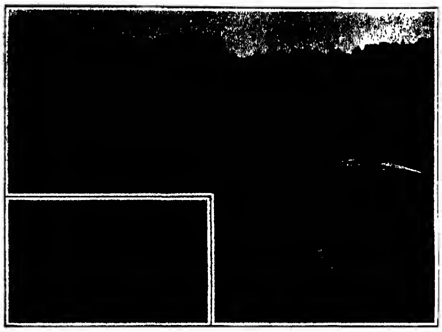
NIGHT SKY: SEPTEMBER AND OCTOBER

A Swimming Machine

AN inventor living near Paris has constructed an apparatus which for lack of a better name we may call a swimming machine. It consists of a light beam six feet long provided with a float at each end. The swimmer supports himself on this device with his feet on pedals under the rear float. By giving the pedals a reciprocating motion, he operates a propeller that drives the machine through the water. The steering is done by the hands and arms. With a device of this sort the swimmer can make a high speed through the water, because his energies are used to best advantage. The apparatus may readily be folded up and transported. The small insert shows the apparatus in use. The harness on the swimmer's back is connected by a wire to the supports of the rear float and enables the operator to gain a better purchase on the pedals.



Propeller driven swimming machine.

Truck for Aeroplanes.

DURING the recent war maneuvers the aeroplanes of the aviation squad were transported to the aviation station by a motor truck of standard make. The work of this motor truck was very satisfactory, considering the fact that it had to travel over bad roads and very rough ground. The aeroplanes, however, had to be completely dismantled in order to stow them on the motor truck. In European countries trucks of special design have been built for the purpose so that the aeroplanes do not have to be dismantled completely, and hence can be assembled more quickly. The accompanying photograph shows a truck of this type exhibited at the Belgian automobile exposition last winter. This truck is a trailer, not being provided with a driving mechanism, but being adapted to be hauled behind a motor truck or an automobile. The truck is designed to take a monoplane from which the planes have been removed, the latter being packed alongside the body of the aeroplane.

Truck for transporting aeroplanes.

The de Lesseps "Wind Wagon."

By T. M. R. von Kéler.

WHILE the idea of driving motor cars by means of an "aeroplane" propeller is not exactly new, the invention of Counte de Lesseps, shown in the accompanying photograph, presents several exceedingly novel features. It is by all odds the most elaborate attempt on the part of a motor car designer to utilize the pushing power of a large two-bladed propeller. The machine is not an ordinary automobile chassis in which the differential and transmission have been temporarily "declutched," so to say, but it is a car designed especially for this sort of propulsion.

The de Lesseps car has no "live axle," and all its four wheels are "free turning." The propeller is driven by a single chain leading from the main shaft to a short jack shaft to which the blades are fastened. Strong guards made of steel tubing and wire netting form a partial protection for persons approaching the whirling propeller blades. These guards are also expected to catch the broken pieces of the propeller blades in case of an accident. The motor is of 40 horse-power. In its long trial run of over 300 miles the car attained a speed of about 62 miles per hour over fairly good roads—a noticeable feature of the trial being that practically no dust was raised by its passage.

This latter very desirable attribute of such a car is easily explained by the absence of the slanting "dust pan," which hangs below the chassis of the ordinary motor car, and which deflects a strong air current directly upon the road surface. Furthermore, there is the free turning of the rear wheels, which in the de Lesseps car perform only a simple rolling motion, while in the axle-driven automobile the rear wheels exert a strong push or "flip" upon the road surface, causing it to disintegrate.

Difficulties which would tend to overbalance these advantages and to retard a general adoption of propeller drive are not missing. Starting the car in a strong headwind would be almost impossible, the forward pull and speed being largely dependent upon the movement of the surrounding atmosphere, in heavy sand or sticky mud it would also be difficult to obtain sufficient tractive power to overcome suction of the mud at the moment of starting. Once the car has been set in motion it is kept going at a small expense of power

Then there is the great danger of steering troubles, induced by the constantly changing speed of the car under changing wind conditions, and by the gyroscopic action of the large propeller, which submits the mechanism to enormous torsional stresses Tests made on the ice here in America with a similar "wind wagon" have shown it to be incapable of taking sharp turns at even moderate speed

While the de Lesseps car may be interesting from an engineering point of view, there appears little danger of its general introduction—at least in its present form.

The de Lesseps car starting a trip from Paris to Lyons.

Black Lightning Flashes

THE accompanying photograph of lightning, showing both bright and black flashes, was taken at Lake Benton, Minnesota, on the night of May 2d, 1912, at midnight The shutter was open one minute, during which time probably several successive flashes occurred.

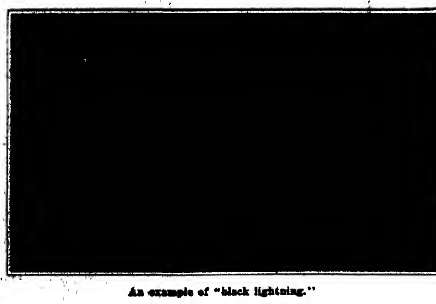
Black flashes are frequently seen in lightning photographs, and the conditions under which they occur are now well understood White flashes with black borders, as shown in the present case, are a characteristic feature of the phenomenon. The black flash does not occur in nature, but is a trick of the photographic plate, and different kinds of plates are sensitive in very different degrees to the process involved. The present picture was probably taken on a film, and shows the phenomenon in a marked degree

As long ago as 1889 Mr A W Clayden, the well-known English photographer, showed how to reproduce this phenomenon in the laboratory (*Philosophical Magazine*, 5th series, vol 28, p 92 94), whence it has since been known as the "Clayden effect" If an electric spark of moderate intensity is photographed, and the plate is subsequently exposed to a very feeble general illumination (e g., with gaslight), the plate, after development, will print an ordinary white flash, if the after-illumination is a little brighter, the spark will not appear on the print at all; and, finally, if the after illumination is still brighter, the spark will print black. In order to get black flashes, therefore, the plate must have been exposed at least twice to the light.

Suppose, now, that a lightning flash has registered its impression on the plate, and before the shutter is closed a second flash occurs in the same field. If the latter is bright enough, the clouds will be lighted up and the light reflected from them will produce the diffuse illumination of the field necessary to produce "reversal" of the original image. That often only the border of a bright flash is reversed is explained by the fact that this is less bright than the "core" of the discharge and is more easily affected by the subsequent illumination of the field

An attempt to explain the chemistry of this process (somewhat too technical to be given here) will be found in the *Verhandlungen der deutschen Physikalischen Gesellschaft*, September 15th, 1911, p. 676.

In photographing lightning for scientific purposes it is desirable to select plates that are as little as possible susceptible to the Clayden effect, for, as stated above, this effect may entirely obliterate certain flashes Tests of a large number of plates from well-known makers were made a few years ago by Dr B Walter, of Hamburg, to determine which are most satisfactory in this respect. (See *Annalen der Physik*, 4te Folge, Band 27, p 92.)



An example of "black lightning."

The Trade-mark as a Business Asset

By W. E. Woodward

[THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer; that it is a symbol of good will, a tangible asset with a determinable money value, that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.

The following is the eighth of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, will include discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark protection.—EDITOR.]

Trade-mark Protection.—VIII.

(Continued from page 165, August 24th, 1912.)

An owner of a valid trade-mark is protected by law in its exclusive use, as he is in the use of any other property that he may own. But to obtain this protection his trade-mark must possess all the essentials of validity, and he must be able to prove infringement, in short, the burden of proof is upon the owner of the trade-mark alleged to have been infringed.

Infringement of a trade-mark is defined in Hesseltine's "Law of Trade-marks and Unfair Trade" as. "An imitation such as would be likely to deceive the ordinary customer in the usual course of trade in the purchase of goods of one person as those of another."

The question of the infringement of a registered trade-mark is covered by sections 16, 17, 18 and 19 of the Act of 1905. Section 16 is quoted here:

Sec 16 That the registration of a trade-mark under the provisions of this act shall be *prima facie* evidence of ownership Any person who shall, without the consent of the owner thereof, reproduce, counterfeit, copy, or colorably imitate any such trade-mark and affix the same to merchandise of substantially the same descriptive properties as those set forth in the registration, or to labels, signs, prints, packages, wrappers, or receptacles intended to be used upon or in connection with the sale of merchandise of substantially the same descriptive properties as those set forth in such registration, and shall use, or shall have used, such reproduction, counterfeit, copy or colorable imitation in commerce among the several tribes, or with foreign nation, or with the Indian tribes, shall be liable to an action for damages therefor at the suit of the owner thereof; and whenever in any such action a verdict is rendered for the plaintiff, the court may enter judgment therein for any sum above the amount found by the verdict as the actual damages, according to the circumstances of the case, not exceeding three times the amount of such verdict, together with the costs

Note that in cases of infringement of a registered trade-mark, suit may be brought in a Federal Court, that triple damages may be collected in case the proof of infringement is established, and the defendant will be forbidden to use the offending mark.

Infringement is a specific violation of the trade-mark statutes It falls under the broader and more general law of unfair business competition, which takes cognizance not only of trade-mark infringement, but also of all other devices of deception by means of which one person trades upon the reputation of another

Nims, in his excellent book on "Unfair Business Competition," says

"The use of a special mark in connection with particular goods or a particular business is a representation that those goods or that business or the goods or business of the person to whom the mark belongs; that they belong to the person to whom the mark has become identified If such representation is false a case of unfair competition exists. The law of trade marks therefore, is merely a specialized branch of the broader doctrine of unfair competition. Relief in trade-mark cases is afforded upon the express ground that every person is entitled to secure such profits as result from a reputation for superior skill, industry, or enterprise, or, in other words, from his good-will But, as has just been seen, this is the precise principle upon which relief is afforded in cases of unfair competition The right of action in technical trade-mark cases is based upon the ground that an exclusive property right in the mark is claimed, and that the mere use of a close imitation of it, by another, *ipso facto* creates a cause for action, regardless of the effect of such use or imitation But the courts in the past have frequently lost sight of the broad general principles of unfair competition and have sought to decide cases of unfair competition pure and simple 'upon principles analogous to trade marks' The owner of a technical trade mark claims it as his, regardless of the effect on others If someone else uses it or imitates it, the owner claims a right of action because the mark is his and his alone"

And further on, in the same volume:

"Unfair competition does not necessarily involve the violation of any exclusive right to use a word, mark, or symbol. It may arise from the use of words, marks or symbols which are free for everybody to use and are not subject to exclusive appropriation by any-one The existence of this right of action depends upon the question of fact, whether what was done in any special case tends to pass off the goods of one man as being those of another, or tends to deprive any one of his rights, This is the only substantial distinction between cases of unfair competition, or passing off actions as they are called in England, and cases of infringement of trade-marks"

This subject is so large and far-reaching that we can touch upon it here only in the most general way, and as incidental only to the question of trade-marks.

Unfair competition, so far as trade-marks are concerned, may take various forms, the most common of which are discussed in the following.

Plain Bare-faced Theft of Trade-marks.

In certain lines of business, notably the liquor, wine and cigar trades, this sort of infringement is very common and organizations of houses dealing in these products have been forced to check it. Many States have enacted laws making the counterfeiting of a labor or a trade-mark a penal offense. Under the Federal law, infringement is not a penal offense, and only civil actions may be brought under this statute.

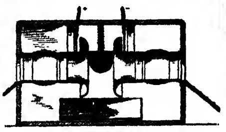
One of the most interesting cases of the adoption of a trade-name belonging to another that has appeared in the Federal courts is that of Wolf Bros. v. Hamilton Brown Shoe Company (165 Federal Rep., 413). Wolf Bros., shoe manufacturers of Cincinnati, had established a common law right to the use of the name "American Girl" as applied to shoes. This mark is not registrable, as it is both geographical and descriptive. The plaintiff has used the mark continuously since 1896. In connection with the wording, there is a lady's head and the phrase: "A shoe as good as its name." Certain styles are designated by numerals, such as 404, 408 and 397. The defendant, a St. Louis company, began to use in 1900 as a trade-mark for shoes, the words "American Lady," with a lady's picture Later on they advertised "American Lady" shoes with the phrases "With the character of the woman" and "The shoe deserves its name" The numbers used by the complainant in designating styles were also taken by the defendant. The defendant, one of the largest shoe manufacturers in the country, advertised the "American Lady" shoe extensively, spending more than one hundred thousand dollars in publicity after suit had been brought by the complainant. On trial of the complainant's suit for damages, brought before the U. S Circuit Court, the defendant's treasurer testified that objection to use of the name had been formally made by the complainant in 1901, but that he had considered a protest from a source so insignificant as something of a joke, and had paid no attention to it. The only difference is the use of "Lady" in the defendant's mark instead of "Girl;" the two being in all other respects essentially the same. Judgment was awarded the complainant The defendant was forbidden to use the "American Lady" mark, and was ordered to turn over to the complainant all profits since the suit begun.

(To be continued.)

RECENTLY PATENTED INVENTIONS.

Electrical Devices.

ELECTRIC RAT EXTERMINATOR.—J. W. M. CARMICHAEL, 831 Commerce St., Wellsburg, W. Va. This exterminator is simple and cheap of construction, and one, which, by means of an electric circuit arranged to be automatically closed by the animal as it passes into and through the apparatus, will

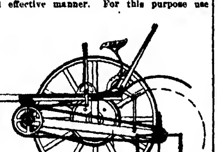


ELECTRIC RAT EXTERMINATOR.

kill the rat. A further object is to construct the apparatus so that the rat as it is killed will fall from the entering passage, and in which the circuit will be automatically opened preparatory to another operation. The engraving shows a longitudinal section view through the apparatus

Of Interest to Farmers.

GROWTH DESTROYER.—H C. SHUBERT and C. L. EVINGTON, Richland, Mo. This invention pertains to agricultural machines, and the aim is to provide a growth destroyer more especially designed for use on land that has been cleared of timber, to destroy the sprouts or returning second growth in a very simple and effective manner. For this purpose use

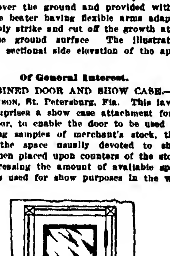


SPROUTS OR GROWTH DESTROYER.

is made of a wheeled vehicle adapted to be moved over the ground and provided with a revoluble beater having flexible arms adapted to forcibly strike and cut off the growth at or near the ground surface The illustration shows a sectional side elevation of the apparatus.

Of General Interest.

COMBINED DOOR AND SHOW CASE.—A. L. JOHNSON, St. Petersburg, Fla. This invention comprises a show case attachment for a store door, to enable the door to be used for exhibiting samples of merchant's stock, thus saving the space usually devoted to show cases when placed upon counters of the store, and increasing the amount of available space which is used for show purposes in the windows. By using glass in the construction, the articles on exhibition can be viewed through either the front or back and articles on the lower shelves can be seen through the upper ones on account of the transparent nature of the material of the shelves. The engraving shows a rear elevation of a store door, with a show case in place thereon.



COMBINED DOOR AND SHOW CASE.

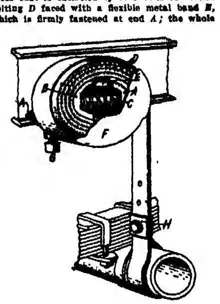
Hardware and Tools.

LINE HOLDER.—G. M. VROOMAN, 113 Fairview Ave., W. New Brighton, S. I., New York. This holder is for use in shingling roofs, and at other localities where it is desired to mark off a series of parallel lines. A series of lines may be marked off across a surface by operating on one side only of the surface. It may be operated from a distance, and the marking line changed from one location to another without making trips across the marked surface in order to regulate or actuate the device

ICE CREAM FREEZER.—H. JURGENS, 420 Fifteenth St., Denver, Col. The intention here is to provide a stationary can into which the cream may be fed continually without interrupting the operation of the movable parts, and further to provide in addition to the ordinary form of dasher and agitator for the ice and bran.

Pertaining to Vehicles.

REBOUND SNUBBER.—CLAUDE H. FOSTER, 1407 E. 40th St., Cleveland, Ohio. This device prevents breakage and excessive rebounding of automobile springs. The circular base is divided into halves, *A* being clamped to the frame of the car and *B* being movable, supported on a stud in the casting *A* by a sleeve, around which is a coil spring *C*. This two-piece base is encircled by four coils of Balata belting *D* faced with a flexible metal band *E*, which is firmly fastened at end *A*; the whole



REBOUND SNUBBER.

being inclosed in a dust-proof steel case. Springs move downward uninterruptedly, but excessive upward movement is retarded by friction and the car is kept from excessive swinging up and down. The device shown herewith is now in general use.

FOUR WHEEL DRIVE.—F. P BERGMAN and H. CLARKE, Cherokee, Okla., care of S. R. Roth, Cherokee, Okla. This invention is an improvement in four wheel drive mechanism, and has for its object the provision of a simple mechanism by means of which power may be applied directly to each of the wheels of a vehicle, without interfering with the turning of the vehicle.

TRACTION WHEEL.—J. BEARD, Veterans Home, Laytonville, Cal This invention refers to wheels for use with road locomotives, traction engines, agricultural implements, etc., and more particularly to a wheel of the above class, which comprises a revoluble rim having radially movable feet, a series of freely movable guide rollers adapted to be engaged by the feet, and arranged to permit a plurality of the feet to come into contact simultaneously with the ground.

SPRING WHEEL.—G. DOERFEL, 2816 E. 27th St., Fruitvale, Oakland, Cal. This wheel employs two elements, one movable relatively to the other, and one of these elements comprising a hub and a bearing ring rigid relatively to each other and spaced concentrically apart; the other comprising two annular members concentric to each other and also spaced apart and acting as a unit, and spring connections of various kinds from one of these elements to the other.

NOTE.—Copies of any of these patents will be furnished by the SCIENTIFIC AMERICAN for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

INQUIRY COLUMN

Inquiry No. 9267. Wanted addresses of manufacturers of metal specialties in connection with plate or window glass.

Inquiry No. 9272. Wanted names and addresses of engravers and mounters of fine quality maps or plans of large cities. Large order.

Inquiry No. 9273. Wanted to buy a globe for a parlor fountain, working on the Heron system.

Inquiry No. 9274. Wanted the name of a manufacturer of a machine to make cushion covers for fruit crates.

Inquiry No. 9275. Wanted name and address of manufacturer of stock patterns of plated job printing presses.

Inquiry No. 9276. Wanted a household convenience and necessity which can be retailed at a profit at a price of from $1.00 to $2.00.

Inquiry No. 9277. Wanted a machine for packing dry batteries.

Inquiry No. 9278. Wanted a machine for separating crab meat from the shell.

Inquiry No. 9279. Wanted a machine for shredding asbestos board.

Inquiry No. 9280. Wanted names and addresses of manufacturers of machinery for stuffing dolls and teddy bears.

Inquiry No. 9281. Wanted to buy machinery for [illegible] walnuts and ivory nuts.

Inquiry No. [illegible]. Wanted name and address of manufacturers of coin-controlled gasoline-dispensing tanks for automobile use.

Inquiry No. [illegible]. Wanted name and address of dealers in powdered Cocoa and Kola nuts in bulk.

Curious Megalithic Monuments of France

(Concluded from page 180.)

The dolmens and roofed alleys of France appear in two forms; either entirely uncovered, or covered partly or wholly by mounds composed of stones, of earth, or of alternate layers of each. Sometimes the base of the mound is surrounded by a circle of stones to keep the mass of earth in place. The orientation of these monuments is very variable. The entrance may be directed toward any point of the horizon, although according to M. Cartailhac it faces the east in the majority of southern dolmens. A flat stone, sometimes provided with a circular, oval or rectangular appature, served as a door and protected the tomb from violation.

To these prehistoric monuments are attached legends and superstitions which are reflected in the popular names of the monuments, Fairies's Rock, Devil's Stone, Giant's Tomb, etc. The Celts and Gauls, impressed by the huge size of the dolmens and menhirs erected by their predecessors, ascribed their construction to gods and heroes, and at a subsequent period the Gallo-Romans saw in them the intervention of Saints. In Gargantua's Tooth, Gargantua's Quoit, Saint Martin's Stone, and others, may be fouud remnants of the old worship of rocks, of which traces are preserved in all Pagan religions. Even Christianity failed to eradicate these beliefs, to which the rural population of Gaul long remained faithful

These megalithic monuments must not be confounded with natural stone monuments, especially the rocking stones, which can be set into oscillation by a touch of the finger. Fig. 2 shows one of these stones, which is situated near Boussac. Contrary to old-time opinion, these rocking stones are simply freaks of nature, involving no human intervention.

A menhir is a crude monolithic pillar, a straight row of menhirs is called a colonnade and a ring of menhirs is called a cromlech. According to M. A. de Mortillet the whole number of French menhirs, including those of the colonnades and cromlechs, is 6,192 The distribution of the menhirs does not correspond to that of the dolmens. Both abound in Brittany, but few menhirs are found in the southern departments which are rich in dolmens.

The menhir of Locmariaquer (Morbihan), which attains the height of 67 feet, is the most remarkable of all. Unfortunately this colossal needle of granite was overthrown, probably by a stroke of lightning, and broken into five pieces, four of which are now lying on the ground. The original weight of the menhir is estimated by some writers at 250 tons, by others at 347 tons. At all events, this was the highest menhir in France. The second in rank, that of Plésidy (Côtes-du-Nord) is only about 37 feet high. A menhir of about 36 feet stands at Plouarzel (Finistère) and one of 34 feet at Louargat (Côtes-du-Nord). The remaining menhirs of Brittany range from 16 to 30 feet in height. Those of Lampary (Fig. 4) and Chênat (Fig. 1), represent the average dimensions. The menhirs of southern and central France are much smaller. That of Davayat, the tallest in Auvergne, is only about 15 feet high

The purpose for which these monuments were erected is still a mystery. Some archæologists regard them as primitive idols, others as monuments erected in commemoration of great historical events. It is quite possible that different menhirs were erected for very different purposes. The gigantic needle of Locmariaquer and the little menhir of six or ten feet in height have little in common with each other. Some of the menhirs may be simple boundary marks, which have no religious significance.

The large menhirs, however, are probably religious monuments. The strange practices which have grown up around them in the course of ages, and which still prevail in some districts, are survivals of ancient religious rites. After

the introduction of Christianity into Gaul, the missionaries, not daring to overthrow these ancient sacred stones, surmounted or marked some of them with crosses.

The most celebrated colonnades are those of Carnac (Morbihan), which extend a length of 19 miles from east to west. They are distributed in three groups, separated by vacant spaces, and designated by the names of the villages of Ménec Kermarie and Kerlescan. The Ménec group comprises 1,169 menhirs, arranged in eleven colonnades and one circle or cromlech. The Kemarie group contains 982 menhirs arranged in ten rows, and the Kerlescan group contains 579 menhirs, of which 39 form a cromlech and the rest are arranged in 13 rows. North of Carnac are extensive colonnades, consisting of 1,120 menhirs arranged in 10 lines and covering an area of 6,900 by 210 feet. The colonnades of Plouharnel, Peumarch, etc., are much smaller.

In other places cromlechs are found isolated and not connected with colonnades and avenues. The most typical monuments of this category are the twin cromlechs of Er-Lanic (Morbihan). The two cromlechs are tangent to each other, and one is now partly covered by the sea, even at low tide. The diameter of the imperfect circles varies from 180 to 197 feet. The numerous polished stone hatchets, pieces of crude pottery, granite millstones and primitive tools found in this vicinity indicate that these cromlechs served some other purpose than the retention of funeral mounds. Many hypotheses have been formed in regard to the purpose of the colonnades and cromlechs. Are they temples of the sun, places of sacrifice, or commemorative monuments? The study of their architecture and of the traditions attached to them will possibly solve the problem some day, but at present serious archeologists are content to classify and compare these remarkable prehistoric ruins, without indulging in fantastic conjectures.

Smoke, the Destroyer

(Concluded from page 181)

draperies and paper are soiled much more quickly in a smoky city than elsewhere. If light paper is used in covering the walls, it must be cleaned every six months and new paper put on every year to keep it looking only half as well as one would wish.

The acid in the soot attacks draperies, rendering them useless in a short time. The extra wear of cleaning materially shortens the life. On interior painting the effect is not as marked because cleaning is done about every so often anyway. But the problem of interior decoration and keeping the outside of a building clean is a problem, indeed, and next to an impossibility in some smoky places. The statement has been made to me by a number of painters that they have done jobs which looked really as bad after two or three days as they did before they were painted. Soot certainly destroys the æsthetic value of paint very quickly. The time which it takes to accomplish the pollution is, of course, dependent upon the amount of soot in the air, the color of the paint, the tar in the soot, etc. The number of paintings required to keep the same building as presentable as in a smoke free city will naturally vary greatly. Cases can be cited where it is necessary to paint three or four times as often as would be required for protection. In the majority of cases in smoky cities the amount of painting is probably doubled. Sometimes it is necessary to remove the soot and the tar and to wash the building before applying the next coat of paint. This washing also removes the paint, often making necessary two coats in place of one for a proper covering. After the wood has received ten to twelve coats it is customary to burn off the paint. This is an additional expense and likewise endangers the house by fire. The action of soot on the wearing qualities of the paint also depends on many factors, involving the chemical composition of the paint and the soot. The soot may be acid, neutral or even slightly alkaline. Places are known where the soot in reality acts as a protective coating, and this is probably the case for the most part. Others claim that it is corrosive to the paint surface, destroying the gloss and rendering it much more easily weathered. This is probably true in those cases where the coal burned contains a lot of sulphur and the soot is consequently very strongly acid.

Feeding the Body With Electricity

AT the Science Advancement Congress, held at Bordeaux, Prof. Bergonié brought out the somewhat startling fact that the electric current can serve to some extent in the place of nourishment for the human body. Should this idea be carried to its fullest limits it may be possible to dispense with taking food and simply remain for a few minutes in a high-frequency electric cage so as to have the body saturated with what might be called electrical nourishment, or in more accurate language the electric currents act to restore energy to the human body in a manner which is analogous to the effect of food. When high frequency currents first began to be used, as Prof. Bergonié says, it was shown by D'Arsonval that these could set up very striking heat effects in the organism, so that the human body is internally heated. Owing to their harmless action, no other effect than development of heat is produced. The liver, heart or brain can receive the high-frequency currents without any bad effect upon their working. Thus the current can supply as large an amount of energy as is desired to the human body, provided the heat is not brought too high so as to cause death of the protoplasm as occurs in Dr. Doyen's electro-coagulation method. But it is not hard to keep within the proper limits, and no danger need occur. With some organisms which are weakened on account of their being deprived of nourishment for any cause, the general temperature may become lowered even by two degrees. A person can thus lose a quantity of heat which is represented by one twelfth of the daily ration of that organism. It is, therefore, a wonderful result to make up for this deficit without calling upon the digestive organs and without increasing one's daily ration, also without introducing any drugs into the blood or tissues. Electricity allows of sending a quantity of energy which may be considerable into the living organism under the form of high-frequency and low-tension currents, and this action can be repeated as often as is needed. He finds that in experiments made at the Bordeaux college, overworked or enfeebled persons, anemics and the like, showed that the current caused a toning up of the system and abolished stomach overwork. Force reappeared and he found a considerable gain in weight. Commenting on this, he remarks that we once thought that chemistry would solve the problem of food, and that we could be nourished by chemical products. But this does not appear to be realized even in this age of progress. Perhaps electricity will now be able to come in where chemistry failed, and in the future ages we will be electrically fed.

Military Aviation Abroad

By the Paris Correspondent of the Scientific American

A BERLIN correspondent of the Paris daily journals states that Prince Henry of Prussia is engaged upon an aerial mitrailleuse which is being worked with in secret, but some of the details are known at present. The mitrailleuse is mounted upon an aeroplane so that it can be aimed directly by the movement of the latter, being placed in front of the pilot's seat upon the framework. It is thus aimed by raising or lowering the aeroplane as a whole by using the rudder, and a side displacement is secured in a like manner. A single pilot thus serves for flying as well as firing, and the recoil takes place always according to the direction of flight so that there is no danger of capsizing. It appears that this is the

result of a programme which the German army has been engaged in following for some months past. Armored aeroplanes are being built and great attention is given to this point, although but little information has transpired. It appears that the army recognizes that the number of its pilots is much less than in France or Russia, and to counterbalance the inferiority in the number of aeroplanes which can be put out, if this statement is to be believed, the army intends to make this up by quality if not by quantity. Eight of the most experienced pilots are selected, and they will have special aeroplanes which act as destroyers and not for scouting purposes like the enemy's flyers. The destroyers will be very rapid and will carry mitrailleuses and other arms with ammunition. In order to make a quick flight they will be fitted with powerful motors of 130 or 140 horse-power, and to avoid shot which might carry as far as 1,500 feet as experiments showed, they will have armor plated parts especially around the pilots, motor, tanks, and steering gear. The armor is heavy enough to stand shot fired as close as 600 feet. According to the programme, the enemy's aeroplanes commence to reconnoiter the front of the German lines. Thereupon the armored aeroplane takes its flight, and as it makes a higher speed of 70 or 80 miles an hour, while the enemy makes only 50 miles an hour, it reaches him after a short pursuit and seeks to destroy the aeroplane. When this is done it comes back to headquarters and is ready to begin another attack.

Admitting that the information about the armored aeroplane is correct, there may be made some exceptions to the above statements. On one hand, it is claimed that the German army will be able to put out as many aeroplanes as the French, and should this be true, the addition of the "destroyers" will give them an advantage, at least for the time. However, it is stated that ordinary aeroplanes will be able to make as high a speed as the destroyers, so that they will be out of danger. The Russian army, in fact, ordered about 100 aeroplanes from the Paris Nieuport establishment about the first of the year, these being of the two-place type, and will be used for scouting purposes. They are to make a speed of 75 miles an hour, so that even should the German aeroplanes have a slightly greater speed, they will not reach the enemy before he is ready to alight in a safe place. Again, the Russian army is also engaged in building aeroplane destroyers of a similar kind, and have already ordered a number of these from a French construction firm.

Salving the Steamer "Jose"

(Concluded from page 178.)

under the "Jose" was a long, tedious and difficult one, that of raising the vessel after the chains had been passed under it was far more delicate and required a great deal of skill based on long experience in such work. The tension on the chains had to be regulated to a nicety so that each would bear its own share of the burden, and here is where the practice of years in wrecking showed itself. No instruments were employed for testing the tension on the chains. Practical judgment and experience alone were used. To raise the wreck the pontoons were filled with water, sinking them as far as practicable, and at low tide the slack of the chains was taken in and their tension adjusted. Then as the tide rose the pontoons were pumped dry, and with the combined lift of the pontoons and the tide, the vessel was raised out of the pocket in which it had lain and was towed off. When it grounded the wreck was allowed to rest on the bottom at high tide, and at low tide the pontoons were filled again, the slack in the chains was taken up and then with the rising of the tide the pontoons were pumped dry and the vessel was lifted enough to carry it farther. This process was repeated until the decks were clear when the divers entered the vessel, and closed all the ports. Then the ship was pumped clear of water and floated.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

The New Dispensation or Development of Children by Environment

EUTHENICS, the sister science of eugenics, deals with race improvement through environment. It studies the hygiene of the present generation, while eugenics deals with race improvement through heredity for future generations.

Euthenics teaches us that diseases themselves are not inherited, but the power to resist disease is inherited, and unless this resistance is present a child is liable to fall a prey to the ever present microbe.

Heredity and environment taken together produce a child's characteristic health, and as heredity is nothing more than stored environment, every mother has a chance to add to that store, so that her child's health can be better than his parents.

The following principles are used to encourage the mother whose child has one parent with a bad heredity:

1. The inheritance from the healthy parent is stronger than the inheritance from the diseased parent.

2. A bad inheritance can be overcome by a good environment.

A mother, whose child has tuberculous inheritance, should take great precautions to prevent him from contracting the disease. First, unless she be tuberculous she should nurse him herself.

Cows milk is the source of fully one half of the cases of intestinal tuberculosis in children, and when this disease is contracted under one year, it is nearly always fatal. The greatest cause of infant mortality is due to the souring or growth of microbes in milk in hot weather.

Many physicians prescribe an artificial milk food for children which requires only the addition of water, to prevent infection. The best way, though, is to avoid milk, unless you are perfectly sure that the cows have been tested for tuberculosis, and unless the milk is germ free or has been pasturized or sterilized.

A child's general diet at infancy, should be beef juice and orange juice in increasing amounts, from a few teaspoonfuls to several ounces from eight months on. From two and a half to three years he should have meat, which is finely scraped, well-mashed potatoes, and stewed fruits. The child should not have a diet composed largely of cereals or starches, for such a diet cannot supply the strength which a child needs for him to develop into a strong man or woman.

Next to the food, comes fresh air. The child should take all his naps out of doors, and at night a window should always be open, but without too much moving currents of air.

As the child grows up he should have out-door games, because such amusements bring appetite, health and sleep.

The next important thing is to prevent contagion. A nurse girl, who has tuberculosis, should never be put in charge of a child, and the child should never be kissed on the mouth, no matter by whom it may be.

All children should be taught to be clean—to prevent all diseases, but especially tuberculosis. The finger nails and hands should be kept especially clean. He should never use a drinking cup that another has used or even a glass that has been fingered.

The Half-mad

INSANITY has been variously defined in different eras and from many viewpoints—those of the scientist, the physician, the lawyer, the psychologist, the philosopher, the man on the street. And little wonder, considering the almost infinite complexity of human psychism. Besides, to define insanity with precision one must first answer the question "What is mind?" Who has ever done that successfully!

All gradations of the perturbed have been made, from the lovably daft to the hopelessly demented. And the point of view has, in the course of civilization constantly been changing. That of the present day is quite ultra-scientific, having been developed from the "rationalism" of Voltaire in the eighteenth century; it is a finding which will certainly be modified by future generations. For it considers many insane, or at least half-mad, who in other ages were rightly lauded as geniuses, saints, benefactors and world-compellers. It ignores the legendary, which is so fundamental in human nature, and so dear to humanity; it takes no account of the emotional, the poetic, the soul-stirring—entities, which after all make living the most worth while.

Prof. J. Grasset, of the University of Montpelier, has in his book "Demi-fous et Demi-responsables," designated as half-insane (Lombroso would have deemed them afflicted with "genius-insanity") such men as Pascal, Comte, Balzac, Hugo, Molière, Wagner, Schiller, Descartes, Cromwell, Goethe, Mozart, Byron, Tolstoi, Ampère, Dante, Columbus—even Shakespeare—and many another. Obviously, when one considers such men *demi-fous*, there is something wrong with the definition. Did St. Paul or St. Francis see visions? What would civilization be if they had not? Did Beethoven "rough-house" the homes of his princely friends who sought to relieve his needs? What matter to any one who has heard the Ninth Symphony? Was Caesar an epileptic? Was Napoleon a degenerate and a hypochondriac? Was poor Chopin's immortal music tinged with the toxemia of his consumption? Was Poe an alcoholic? Schopenhauer a misanthrope? Did Newton abstractedly stick his *fiancée's* finger into his lighted pipe? (He died a bachelor.) Did Dr. Holmes' neighbors doubt his sanity when he put out (so it is chronicled) a sign "Small fevers thankfully received?" Darwin used to surprise his friends by starting all sorts of apparently crazy experiments. Of what matter all these things; of what use to call such men as these neurotics, or hysterics or *demi-fous?* Where would humankind be to-day had not they, and such as they, lived? Who would not, if he could, be in such company?

Grasset most wisely refuses, as is generally done, to divide humanity into two hard and fast groups, the sane and the insane; the group which is or should be placed in confinement, and that which confines it. Part of his work is given to the discussion of Semi-responsibility, Limited Responsibility and Attenuated Responsibility, to the end that such distinctions may find place in French jurisprudence. It seems they have already been accepted in many continental courts, though not at all in our own or in those of Great Britain.

Limitations of the Aeroplane

SURFACES are measured in square feet; volumes in cubic feet. An aeroplane is a surface horizontally driven through the air. The amount which it can support varies with the speed and with the area of that surface. An increase in the weight to be supported necessitates a considerable increase in the area of the supporting surface. Although the cubical contents of the weight may increase only slightly, the number of square feet in the supporting surface may increase considerably. For the present at least there is a limit to the size of supporting surfaces. As it is, the difficulty of properly securing and holding in place the wings of a modern monoplane is such that there is little, if any, room for that factor of safety which is considered so essential in the construction of bridges and tall buildings. There is good reason to believe that some of the most serious accidents which have occurred in the last year have been due to the collapse of improperly supported wings.

Great loads, as the history of transportation teaches us, can be economically carried only by great machines. That is the lesson taught by the modern 40,000-ton steamer and the 425-ton locomotive. Small crews, controlling machinery of enormous power, are able to guide gigantic loads safely to their destinations. At present the aeroplane is piloted as a rule by one man, and it carries one or two passengers only. For that reason, if the aeroplane of to-day were to be used for passenger transportation, an exorbitant fare would have to be charged. Only by increasing the size of the aeroplane vastly will it be possible to use it as a means of commercial transport; and that increase in size is impossible because of the difficulty of increasing the size of the supporting surfaces and of [illegible] them by present methods.

Although it is impossible to [illegible] machine having a supporting surface [illegible] for commercial purposes, [illegible] time a thousand small aeroplanes so as to form one immense supporting surface. The one thousand motors of these machines would be distributed evenly over the whole surface and the one thousand propellers, each connected with its own motor, would be placed above and below the combined surface. In this possible increase of size the designer would be confronted with the necessity of placing the one thousand rudders all along the rear edge, and the further necessity of placing these rudders not only along the rear edge, but at a considerable distance back, and of supporting them in suitable framework. Difficulties equally formidable would arise in properly disposing of and providing operating means for the wing tips.

It is not inconceivable that one hundred, and possibly more, passengers might be carried by a machine thus constructed. It is probable that the conglomerate machine would rise from the ground and fly for some time on a perfectly calm day. To start it, however, would be no easy matter. No doubt it would be necessary to mount the machine on a series of small wheels running on many parallel rails. Landing would not be out of the question in a perfect calm; but in a breeze it might be fraught with disaster. Even in slightly disturbed air such a combined machine would not be absolutely safe. So huge would be the supporting surface that the air pressure would not be evenly distributed. Stresses might be set up which might well break the machine in flight.

Imagine in place of this huge combined surface a flock of aeroplanes flying closely together in the same horizontal plane, assuming that the wash of the propellers would not interfere. A gust which happened to strike the aeroplanes of one side only would raise them above the horizontal plane in which they were all flying. If the flock of aeroplanes were rigidly connected, it is manifest that the connections would snap. It is apparent that an aeroplane's carrying capacity increases in proportion to its surface, and that the engineering safety of a flying machine decreases in exact proportion to the surface exposed to the wind.

None of these objections applies to the dirigible airship. There is no engineering difficulty in constructing a gas bag of any size. Indeed, the same advantages that can be claimed for the large steamship and the large locomotive can be claimed with equal force for the large dirigible. Even now, when the cost of constructing and operating a dirigible is alarming, the advantage is all with the gas bag when it comes to carrying loads cheaply. All the resources of modern engineering can be employed in the airship to obtain great strength with very little weight. As the linear dimensions of the airship increases, its surface decreases in proportion to the lift. The impossibility of increasing the vertical dimensions of an aeroplane without increasing weight that has no lifting effect, confines the engineer to an extremely shallow girder depth, which is the real reason of the aeroplane's frailty. On the other hand, the dirigible, with its great girder depth in every direction, for the same proportionate weight can be made remarkably strong. In a dirigible size counts in every direction; a linear increase up and down means just as much lift as a linear increase fore and aft, or right and left.

If it were possible to build an aeroplane of great size without materially increasing its weight and frailty, it would be possible simply to carry many passengers with a few trained pilots and to fly somewhat faster and for somewhat longer periods than is at present possible with a small machine. In a very large aeroplane the load can be cut down, to a certain extent, in favor of more powerful motors and more fuel. In the small machine this would be equivalent to amputating legs and arms. In stability, safety and navigability, aeroplanes gain by a comparatively moderate increase in size, which might render it possible to carry in comfort several pilots, engineers, and motors, and to install elaborate controlling devices and navigating instruments. The possibility of increasing the size, however, is soon brought to a definite limit, for the reasons given.

The Northeast Passage

BARON NORDENSKJOLD'S classic feat of sailing completely around the northern coasts of Europe and Asia, accomplished in 1878-[illegible], is likely to be repeated in the near future. As already stated in these columns, the Russian ice-breakers "Taimyr" and "Waigatsch," now engaged in a surveying expedition along the coasts of Kamtchatka and arctic Siberia, may possibly continue westward all the way to Archangel, via the Arctic Ocean. A much more elaborate expedition, however, is being organized in Germany by Lieut. Schröder-Stranz, who proposes not only to make the Northeast Passage, but to spend three or four years in the journey, carrying out extensive scientific researches en route.

[illegible]

[illegible]—[illegible] are [illegible] as [illegible] from the [illegible] wheel [illegible]. This [illegible] with the [illegible] is eventually [illegible] in constructing [illegible].

[illegible] for the Great Lakes.—It has been [illegible] a [illegible]-ton boat is being built for the [illegible] Company, which will be [illegible] horse-power Diesel engine coupled [illegible] current generator. This current will [illegible] induction motors connected to the [illegible]. The shaft will be driven at a speed of [illegible] revolutions per minute. The induction [illegible] controlled by the pilot by means of [illegible] on the bridge.

Fishing with a Trolley-wire.—The sale of large quantities of fish by dealers and peddlers in Lafayette, Ind., says the *Electrical World*, recently attracted the attention of the fish and game warden of Tippecanoe County, who, after investigation, assured himself that no seines or nets were in use in his district. Setting out to ascertain the source of the unusual supply of fish, he discovered two men near an interurban railway bridge, one of whom from time to time indulged in the extraordinary practice of striking his fishing pole against the trolley wire, after which the other would gather in a boatload of the dead and stunned fish which floated to the surface. Investigation showed that an insulated wire ran down the fish pole and dipped into the water under the bridge. The 500-volt contact with the trolley served to electrocute all fish near the wire, killing them outright, it is declared, instead of stunning them as in the case of dynamiting.

Trackless Trolleys for Shunting.—An interesting application of trackless trolleys is being made at Altona, Germany, for the shunting of freight cars. The fireless locomotives in use since 1909 will be replaced by trackless tractors operated by means of trolleys pressed by a rigid rod against a double pole overhead line. The trolley, arranged on the roof of the tractor, is designed for deviating on either side to a maximum distance of 3½ meters (11½ feet), so as to allow the tractor to travel on either track. A single overhead line thus suffices for the shunting service, and the loading of cars is not interfered with. The tractor, which is 8 tons in weight, has been designed for handling up to 6 cars with their full load at a speed of 3 kilometers to 6 kilometers (1.86 to 3.73 miles) and is worked by a 35 horse-power continuous current motor at 550 volts, driving all four wheels through a 10:1 worm gear. The coupling device is operated from the driver's stand, so that the brakeman need not pass between the buffers. The shunting line is 1.2 kilometers (¾ mile) long, and reaches as far as the boundary of Hamburg.

Telephones in the United States and Europe.—According to a bulletin issued by the New York Telephone and Telegraph Company, the United States leads the world in the total number of telephones by a wide margin. There are in the United States 67.4 per cent of all the telephones, and only 26.3 per cent in Europe. As against our seven and one half million telephones, the German Empire has but little over one million, while Great Britain comes next with nearly 649,000 and France third with 232,700. There are in New York city alone, more telephones than may be found in Belgium, Norway, Denmark, Hungary, Italy and the Netherlands combined. While Chicago alone has more telephones than France, and Boston has more than Austria. *L'Illustration*, of Paris, gives the following statistics, showing the number of telephones in seventeen of the principal cities in Europe in 1911, and the ratio of inhabitants to each:

	Number of Instruments.	Number of Persons to Each Instrument.
Stockholm	72,000	4.7
Copenhagen	[illegible]	11.4
Christiania	[illegible]	14.2
Stuttgart	[illegible]	15.5
Berlin	[illegible]	16.0
Berne	[illegible]	18.3
Munich	[illegible]	22.1
London	[illegible]	26.3
The Hague	[illegible]	30.1
Paris	[illegible]	35.7
[illegible]	[illegible]	37.9
[illegible]	[illegible]	39.4
[illegible]	[illegible]	44.4
[illegible]	[illegible]	55.0
[illegible]	[illegible]	66.5
[illegible]	[illegible]	112.9
[illegible]	[illegible]	152.0

Science

Dust Laying.—The Highway Department of the city of Leeds, England, has recently treated portions of a macadam roadway with granular calcium chloride to combat the dust. Solutions of the latter had previously been tried at greater cost and without such satisfactory results. The road is first well swept and two applications of the chloride are made on succeeding evenings of about ½ pound per yard.

A Great Reservoir for Buenos Aires.—According to the London *Financial Times* the largest elevated reservoir in the world is about to be erected at Caballito, near Buenos Aires, in connection with the sanitary improvement schemes of the Argentine capital. It will consist of three tiers of wrought-iron tanks supported on cast-iron columns embedded in heavy concrete foundations. The total capacity will be 16,000,000 gallons, and the structure will be 128 feet high, from the base of the columns to the top of the roof. It will contain 15,409 tons of iron and steel. The contract has been awarded in England.

Acid-proof Iron Composition.—Iron alloys containing a certain percentage of chromium are usually employed in the manufacture of articles and apparatus which should resist the action of acids. These compositions are, however, not absolutely acid proof. Recently the well-known German metallurgist, Prof. Borchers of Aix-la-Chapelle, discovered that by adding molybdenum to an iron composition containing more than 10 per cent chromium, in amounts of 2-5 per cent, an absolutely acid-proof composition can be obtained. It is essential, however, that the iron be free from carbon, or at least nearly so. A composition containing 35 per cent iron, 60 per cent chromium and 5 per cent molybdenum, it is claimed, remains unaffected even by hot aqua regia. This alloy has the tenacity of cast iron and can be worked like the latter. Titanium and vanadium, may be used instead of molybdenum, but the latter is preferable.

Meteorological Stations in Antarctica.—With reference to a persistent rumor of great interest to meteorologists, Mr. H. A. Hunt, director of the meteorological service of Australia, says in a personal letter: "There was some talk before the Mawson Expedition went south about establishing a permanent meteorological station on the coast of Antarctica, but what the probabilities or even possibilities are will not be known until the expedition returns and reports upon conditions down there." A much bolder plan recently set forth by Admiral Peary in an American magazine contemplates the establishment and maintenance for a year of a scientific station at the South Pole itself. Meteorological observations would be the most important part of its programme. From several other quarters come hints of the fact that there is a decided drift of opinion toward the inauguration of a campaign of meteorological observations at fixed stations in south polar regions analogous to those carried out in the arctic regions in 1881-83.

English Seaweed for Trimming Hats.—According to a recent number of the *Daily Consular and Trade Reports* a rather unusual industry along the Kentish coast has come to public attention through a complaint lodged with the Kent Fisheries Committee. The inhabitants of the Isle of Grain and the adjoining districts on the east coast of Kent, have for many years been collecting a white seaweed that is washed up along the shore, which seaweed has been used by London and provincial milliners as a trimming for women's hats. This, it seems, has grown into a profitable industry during the winter months, when farm work is not to be had. Its continuance is threatened by the practice of trawlers who attach barbed wires to their trawls and gather the white seaweed before it is ripe, selling the algæ thus collected at a very low figure. In the ordinary way, the seaweed falls off from the roots and is washed ashore but the trawls pull it up by the roots and thus destroy the source of supply, besides leaving nothing for the islanders to collect but the refuse that has been thrown back into the sea by the trawlers. It was asked, among other things, that a closed season for the weed be adopted.

The Iron Mountain of Durango, Mexico.—The Cerro Mercado, as it is called after its discover, Vasquez del Mercado, is described in a recent consular report. Humboldt pronounced it the eighth wonder of the world. The mountain rises about 400 feet abruptly from the plain, is 1¼ miles long, from a third to a half mile wide, and is practically a solid mass of iron ore, of 60 to 75 per cent iron. It is estimated that there is fully 500 million tons of iron ore above the surface of the surrounding plain, besides vast deposits beneath, probably extending [illegible] under the city of Durango. The most [illegible] concerning these rich deposits, is that all [illegible] to work them profitably have been failures for [illegible], especially the long haul to market and the [illegible] cost of fuel. The new Durango-Llano [illegible], now approaching completion, will [illegible] the problem, as it taps a timber country and the waste from timber cutting is expected to supply [illegible] to use in smelting.

Aeronautics

Delivering a Flying Machine by Air.—A Caudron biplane was recently delivered by the maker to Commander Felix at St. Cyr. The distance from Crotoy to the point of delivery was ninety-six miles, which was covered in one hour and a half at an altitude of about four thousand feet.

The Talking Machine and the Aeroplane.—A novel use was made of the talking machine recently in a Farman biplane. A passenger dictated his observations, which were made on a record of specially strong material. This was then carefully wrapped and thrown to the ground, where the record was reproduced. How successful the experiment was, we are unable to learn.

Launcher for Aeroplanes.—In patent No. 1,033,148, to W. A. Bond of Lynn, Mass., assigned to Andrew M. Johnson of Lynn, there is shown a carriage adapted to support a flying machine. This carriage swings horizontally about a vertical axis and when the desired speed of the carriage is obtained, the aviator releases the flying machine so it can be thrown off from the swinging carriage.

A Splendid Record for Military Aviators.—Lieuts. Varcin and Battini, who are among the leading military pilots of the Maurice Farman aeroplanes, recently returned to the St. Cyr aerodrome after a six months' absence, during which they were engaged in scouting work of various kinds with the Mailly camp as a center. What is to be noticed is that they covered more than 12,000 miles and took about 600 passengers on these trips, these being officers who acted as scouts. All the flights took place without any accident and the aeroplanes are in good condition.

French Wireless Experiments.—The French officers are doing some very good work with aeroplanes carrying wireless apparatus and within a recent period the results are improving. The latest experiments were made by Lieut. M. de Varennes. Mounted on a Farman aeroplane he left the St. Cyr grounds near Versailles, carrying the telegraph operator Duriveau. He made a flight to Amiens, and was able to keep up wireless connection with the starting point when at a distance of 50 miles. No doubt a greater distance could have been covered but a violent storm prevented any further work on that day. Seeing that St. Cyr lies in a deep valley, the experiment was a more difficult one.

A French Military Postal Service.—A military aerial postal service is being started in the French army, and during the first trials the results showed all that could be expected. Lieut. Nicaud, mounted on a Farman biplane with Gnome motor, taking the officer Million as observer, made a flight at 6:45 A. M. from the Verdun camp, and after a trip at a very high altitude above the country in the east of France, he made a landing at the town of Nancy which is one of the leading military centers near the eastern frontier. The officers are charged with the postal service for the army and take letters which have a special aviation stamp upon them. There is no doubt that this service will be extended in the future.

Military Aviation in Russia.—The Russian army is actively taking up the aeroplane question at present. Not long ago two of the officers made a brilliant performance. Capt. Andredi is the first to make the flight between Sebastopol, Odessa, Moscow and St. Petersburg, covering no less than 1,800 miles on this occasion. Lieut. Dibowski also made a cross-county flight of nearly the same distance, both upon Nieuport monoplanes. The war department is taking measures to have aeroplanes fly in connection with the coming military maneuvers, and they are to be used alone, without employing airships on this occasion. At the Klementieff artillery firing grounds near Moscow, aeroplanes are soon to be used for observing and reporting the effect of the firing, and at the same point tests as to firing upon aerial objects will be carried on, using kites drawn by automobiles as a mark in the first place.

The English Military Competition.—In a review of the military competition held at Salisbury Plains last August, the editor of *Flight* comments: "Some of the entrants have lost many a brilliant opportunity of impressing the authorities with the capabilities of their machines. True, the weather conditions have been exceptionally bad, but we have seen the spectacle of a whole Flying Corps waiting and watching in vain for flights which, while not in the nature of observed tests, would nevertheless have impressed the army authorities with a sense of what may be called the weatherliness of the modern aeroplane. There is a difference between taking what are really legitimate risks and staying in the hangars with an obvious idea that prizes rather than orders for machines were the main object in view." This seems to have been the chief cause for criticism. *Flight* also points out that once more the need of an efficient, trustworthy engine was brought to view. Serious motor defects prevented at least two machines from accomplishing anything noteworthy. Others were far from economical in the consumption of lubricating oil.

A Novel Use of Cement in Sculpture

How the Statue to the American Indian Was Built

By John G. Prasuhn

MANY articles of literary merit have been written on Mr. Lorado Taft's concrete statue to the American Indian, but these have not made quite clear the technical side of the question—the methods employed in the construction. The writer, as builder, has been requested to set forth in simple technical terms the methods used in the building of this—so far as the writer is aware—the first heroic cement statue, which was dedicated near Oregon, Ill., on July 1st, 1911, and which has been open to the public view and criticism ever since the huge plaster mold was taken off in the early spring.

This statue, standing on Eagle's Nest Bluff, 250 feet above the Rock River, is 48 feet 4 inches in height. Five feet of the 14-foot 8-inch pedestal is exposed. From the end of the steel reinforcing rods, 2 feet in solid rock, to the top of the head it measures an even 60 feet. The statue contains about two tons of twisted steel reinforcing rods and approximately 238 cubic yards of concrete, twenty tons of which are one-fourth inch to dust pink granite screenings for the surface, giving it the appearance of a granite statue.

Approximately 65,000 gallons of water were pumped up from the river for maintaining two steam engines, and for mixing the cement. Four hundred and twelve barrels of Portland cement were used and the mixture was as follows: for the base 1 and 5; for the pedestal and steps going down into the statue, 1 and 4; for the figure, 1 and 3, and granite screenings, 1 to 1½, mixed with a water-proofing compound.

As is customary with most sculptors, the idea of a new work is expressed in the form of a sketch model. In this case the first model was only 8 inches high. The next size was 2 feet, and the third size 6 feet. This last served as the working model. Then a system was devised by which the enlargement was made, and when finished the enlargement was an exact duplicate of the 6-foot model, increased seven times.

In locating the site, a 24-foot silhouette was built, which was found to be too small from the point of view desired. Then a light 42-foot structure was erected on a farm-wagon, and the wagon was drawn around until the proper location was established.

The site having been chosen, a square central tower was built to the height of 38 feet and anchored with guy wires. Plans for enlarging the model were drawn on the model by outlining all straight lines and flat surfaces, and numbering the points with a specially constructed machine, at the termination of these straight lines and flat surfaces. A section of the surface of the model could be enlarged on the ground and drawn up by a rope, and nailed in place to correspond to the model. After all the points were made to correspond to the plan on the working model, wire netting was used for the curves; this in turn was covered with 200 yards of burlap for a surface, the burlap being pinned to the wire with nails at close intervals.

The wooden structure covered with wire netting.

The mold suspended over the excavation.

Hoisting the temporary head with a specially constructed derrick.

A specially constructed derrick was used for the hoisting and setting of the temporary head, which had been previously modeled. This served two important purposes—that of marking the precise location on the statue, and of facilitating the joining of the piece mold of the head to the mold of the figure. After the head had been placed the figure was turned 15 degrees to the right to present a clearer profile from the bluff road. The final modeling was now done and the surface was given a thin coat of plaster to stiffen the burlap, and then a coat of clay-water to insure its release from the mold later on. Both coatings were applied with a force pump.

The mold on the figure was now made of plaster and fiber supported by four 30-foot I-beams blocked up on cribbing timbers on a level with the top of the future pedestal. Every 4 or 6 square feet of the mold had independent bracing directly from the timbers on the I-beams, with strutting, cross bracing and hoops around the barrel-like structure, tending to equalize the outward strains imposed by the cement. The structure was built to shoulder level, the piece-mold fitted to the head and neck, and the two joined together in such a way as to be interlocking and self-supporting after the head had been removed and lowered in the same manner as it had been hoisted up.

Excavating was carried on at the same time that the mold was being made. While this was being done the figure was shored up by timbers from the solid rock 11 feet below the ground level. The central tower was retained as a scaffolding until the piece-mold of the head had been fitted. The interior was patched and cleaned, and the interior of the mold was given two coats, one of wall size, and one of paraffine grease; the former to keep the plaster mold from absorbing the water from the cement, and the latter to insure its release.

The remaining scaffolding was then taken out

(Concluded on page [illegible].)

Concrete statue of an American Indian at Oregon, Ill.

Taking off the piece mold.

Chopping off the mold.

A Railway Car Driven by Gas and Electricity

A Substitute for Steam Trains Where the Traffic is Light

By the Berlin Correspondent of the Scientific American

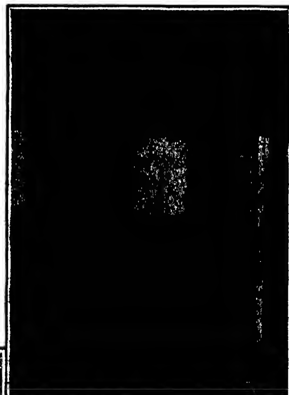
THE Prussian State Railways have for some time given special attention to the question of adopting motor railway cars on lines where there is little traffic. After carrying out preliminary trials with steam-driven motor coaches, twin storage battery cars were used on a large scale, while more recently gasoline-electric cars are being adopted.

The first car of this type was placed in commission in the year 1907. In view of the experience gained with this coach, the gas-electric set was rearranged under the supervision of Mr. Wittfeld, expert to the Ministry of Public Works. Successful trial journeys show that the new coach offers a very satisfactory solution of the question.

The car body is supported on two 2-axle bogie trucks which are provided with triple springs. In order to prevent the vibrations set up by the motor from being transmitted to the car and to insure a ready access to the generating set for the purpose of inspection, both the combustion motor and the shunt-wound dynamo employed for generating the electric current, together with its exciter, are mounted on one bogie truck.

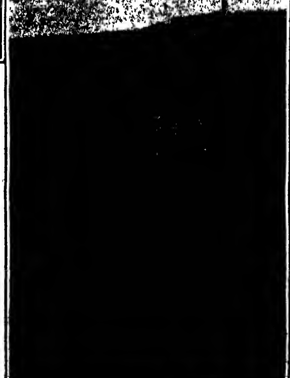
The car body, which is 10,495 millimeters in length, accommodates a total of 95 passengers in a third and a fourth class compartment, and has in addition a driver's compartment at each end. Besides the apparatus required for the control and braking of the car these compartments contain four and five folding seats, respectively, and serve for carrying heavy luggage which cannot be taken into the passengers' compartment.

Apparatus in the driver's compartment.



A new gasoline electric railway car under test on the Prussian State Railways.

A compressed-air brake of the Knorr type and a hand spindle brake are provided, both of which can be operated from either driver's compartment. The car is heated by water coming from the gasoline engine, which, before passing to the radiator mounted on the roof of the coach, flows through coils in the driver's and passengers' compartments. The gasoline engine, which was constructed by the Neue Automobile Gesellschaft, is of 4 cylinder type, and produces 120 horse-power when running at a speed of 700 revolutions per minute. The motor is under the control of a centrifugal governor, but is fitted with a device by means of which the speed at no load can be reduced to 250 revolutions per minute. This device is operated automatically from the controller. The cylinders are cast in pairs; the valves are all placed on one side and are actuated from a common shaft. The admission and outlet valves are of exactly the same dimensions and are interchangeable. The upper half of the crank-case comprises large openings at the side for inspecting the crank mechanism. The crank-shaft itself has four cranks set at angles of 90 degrees to one another, and is supported in bearings at three points. All crank-shaft bearings are placed on the upper half of the crank-case so that on removing the lower half, which is constructed of aluminium, the whole mechanism becomes accessible. A special point was made of obtaining lightness combined with great strength in order to keep the vibrations set up by the momentum of the masses as low as possible. A compressor fitted directly to the motor generates the compressed air required for braking the car and starting the motor. The current for the arc ignition is supplied by a Bosch high-tension magneto apparatus; an ordinary battery ignition is provided as a stand-by. All four cylinders are fed from a spray carbureter which draws in hot air from a pre-heater built around the exhaust pipe. All the apparatus and auxiliary mechanisms mounted on the motor, such as the carbureter, ignition apparatus, cooling water pump, compressor, etc., are so constructed that they can be removed separately after loosening a few screws.



The 120 horse-power generating set.

The combustion motor is coupled to the shunt wound dynamo generating power, by means of a flexible leather link coupling. The dynamo has a continuous output of 66 kilowatts at 700 revolutions per minute, giving 220 amperes normal current at a pressure of 300 volts; it can give 580 amperes for a period of 30 seconds. Commutating poles are provided to insure sparkless running at all loads. The dynamo is suspended in the frame of the leading bogie truck, and is totally inclosed, it is cooled artificially by means of a Sirocco centrifugal fan. The exciter current is supplied by a compound-wound exciter having an output of 2.5 kilowatts at a pressure of 70 volts, which is mounted on the extended shaft of the dynamo.

The car is driven by two railway motors, which in accordance with the regulations of the German Society of Engineers, each have an hourly rating of 82 horse-power at a pressure of 300 volts and a current of 230 amperes when running at a speed of 600 revolutions per minute. With a gearing ratio of 1:4.315, the motors are capable of imparting a maximum speed to the coach, which has a total weight of 55 tons, including the passengers, of 65 kilometers (40 miles) per hour on the level.

The connections of the electrical equipment are carried out on the Ward-Leonard system, by altering the voltage of the generator; this arrangement meets all requirements of the service in a most perfect manner. The generator can, in fact, give at starting, when great tractive efforts are required, heavy currents at a low voltage, and the exact voltage can be obtained at the generator terminals in accordance with the speed of the motor. The combustion motor thus can always be run at a practically constant load and, therefore, at the most favorable speed and with the most economical fuel consumption.

The current for lighting the interior of the car and the signal lamps is supplied by the exciter and the battery connected in parallel with it when the generator set works at full speed. At a lower speed, and in particular when stopping at stations, the exciter is automatically switched off the lighting circuit, by means of a self-acting switch, when the battery alone feeds the lighting mains. The current necessary for the ignition of the combustion motor, for the signal bell and the motor siren is taken from the battery; the charging of the battery is effected by connecting it to the exciter.

This car was until recently placed at the disposal of the chief railway workshop, and has made a number of trial journeys on the Tempelhof-Zossen line.

Recent Improvements in Electric Vehicles

A Review of Important Patents Granted Within the Last Year

IT is remarkable to note the extraordinary favor with which the electrical vehicle is being accepted in the commercial world to-day. This is due to two facts, first, the natural and inherent advantages it has, because of extreme simplicity, and second, because it is being developed and manufactured by reliable and conscientious firms who have carefully developed it, and who invariably guarantee their products.

But popular as the electrical vehicle is at present it is bound to find far greater favor as its advantages become more appreciated. Furthermore, many small improvements and some important ones have been made recently that all tend to make it a more useful and serviceable piece of machinery. These are not radical changes in design or makeup; for the very first cars manufactured are quite similar to the most improved product to-day.

The first thing that strikes one is the ease of control, due to the fact that the electric motor requires no shiftable gears and no clutch mechanism. Starting is as simple and requires no more effort than turning on of an electric fan. By the use of a controller similar in principle to that used on the ordinary street car all the variations in speed up to full speed ahead or reverse can be obtained.

The use of the electric motor does away with noise, odor and jar that is a natural consequence of use of the gasoline engine. The absence of jerks and jars gives longer life of the machinery, saves greatly on tires, and the metal parts of the frame are not subject to crystallizing and becoming brittle as are corresponding parts of a gasoline car due to the incessant vibration.

In fact the mechanism of an electric car is so simple that there are really only two things upon which there can be any extensive improvement, i. e., the battery and the motor.

As for the recent improvements in the battery, no less a genius than Thomas A. Edison, the greatest American inventor, has done much for the electrical vehicle in bringing out the nickel-iron storage battery. Edison's problem was to make a compact battery which would be of less weight and of greater capacity than the previous lead battery. The old lead batteries were extremely heavy and had to be handled very carefully as they were quite fragile and subject to many diseases of all kinds which made handling of an electrical vehicle somewhat problematical. Edison's battery is just half as heavy as a similar capacity battery of the old lead type. Hence, it is possible to carry more "battery" and to increase the m age for a single charge. Only a few years ago the mileage radius of the pleasure vehicle was not over 25 miles, now with the Edison battery it is between 65 and 100 miles.

Another improvement (patent Pieper No. 1,026,827) makes it possible to charge the storage battery while the car is descending a grade. This allows "braking" of the car without actually applying the brakes, thus saving wear and at the same time storing up energy. The control switch of this motor is so arranged, in running down hill, that the batteries are automatically connected with the motor as soon as the voltage is great enough to charge the battery.

One drawback that has often been urged against electrical vehicles has been that it is not always convenient to obtain suitable charging current. In most cities lighting circuits are supplied with alternating current, which is unsuitable for charging batteries. One ingenious inventor (Bender No. 1,017,198) has solved this difficulty. He employs a motor made of two parts. One part is in reality an alternating current motor coupled directly on the same shaft as the other part, which is an ordinary direct current motor.

By means of levers the motor shaft is disconnected from the driving shaft, and at the same time a controller switch is so conditioned that the alternating current motor can be run from ordinary 110-volt lighting circuits, turning on the same shaft with itself the direct current motor, which now becomes a generator and charges the storage battery. An automatic trip is arranged to shut off the machine and disconnect it entirely when the battery is fully charged. This invention promises to increase the field of use of the electrical vehicle, for the alternating current motor can be arranged to run on any desired circuit, but still the batteries can be charged in the usual way if desired. In ordinary use the alternating current motor acts as a fly-wheel and adds but a very little weight.

There have been developed within the last year several clever schemes to cut off the charging current when the storage battery has been fully charged. One inventor takes note of the fact that as soon as the batteries are fully charged they begin to give off gas. A rubber tube is connected with the vent of the cells and this leads to a pressure gage which opens the charging circuit when the gas pressure rises above a certain value.

Another inventor uses the increase in density of the liquid in the cells as a means for determining the extent to which the cells are charged and for cutting off charging current when the battery is fully charged.

Edison has invented an ingenious scheme to prevent the solution in the battery from passing off in gas during charging. The gas that is given off is caused by decomposition of the water. Now by putting a fine platinum wire inside the cell, and heating it while charging current is on, it is possible to cause the gases to recombine into water. Thus loss of liquid is prevented and refilling becomes necessary only at long intervals, if ever.

Another improvement of considerable note has been made in the transmission of power from the motor to the wheels. In most makes of cars in the past it has been the practice to use a chain drive. This is still most widely used on trucks and commercial vehicles, as the slight noise is of little consequence. But shaft drive is now being employed by several of the most prominent manufacturers, as it is silent and can be completely inclosed, giving a pleasing and highly finished appearance. To surpass this another ingenious inventor has patented a scheme whereby the motor is mounted concentrically with the rear axle and is entirely inclosed by the housing of the rear axle. The casing appears no larger than the ordinary differential housing on a gasoline car. The casing is made watertight and the inventor states that he can run the car right through a stream even with the wheels and motor completely under water without the least damage.

In commercial vehicles it is important to have considerable tractive or pulling power, especially where there are no pavements. This has been attended to by several inventors, one inventor has perfected a scheme whereby power is applied to all four wheels at the same time. This is arranged so as not to interfere at all with steering, and is a valuable improvement. Another inventor has added two more wheels, making six in all, and has arranged to have all of them driven, thus obtaining a great tractive effort at all times, regardless of the position of the car.

Oil-mixed Portland Cement Concrete

ORDINARY Portland cement concrete, because of its absorptive qualities, is used in some structures with only partial success. When made proof against the permeation of moisture, not only is its field of usefulness rendered more universal, but its efficiency is likewise greatly increased. A bulletin from the pen of Logan Waller Page, director of the Office of Public Roads of the United States Department of Agriculture, explains a very simple method for damp-proofing concrete by the incorporation of mineral oil residuum with the ordinary concrete mixture. It also describes the application of oil-mixed Portland cement concrete to several much used types of structures in which a damp-proofed building material will be of benefit.

While experimenting in the Office of Public Roads in an attempt to develop a non-absorbent, resilient, and dustless road material, one capable of withstanding the severe shearing and raveling action of automobile traffic, Mr. Page's investigations led him into a very promising discovery. He found that, when a heavy residual oil was mixed with Portland cement paste it entirely disappeared in the mixture, and, furthermore, did not separate from the other ingredients after the cement had become hard. The possibilities of oil cement mixtures for water-proofing purposes were recognized and extensive laboratory tests were immediately begun to determine the physical properties of concrete and mortar containing various quantities of oil mixtures.

Many valuable data have been obtained from these investigations. The damp-proofing properties of concrete mixtures containing oil have been demonstrated very definitely by laboratory and by service tests, which establish this material as one of great merit for certain types of concrete construction. It has also been shown that the admixture of oil is not detrimental to the tensile strength of mortar composed of one part of cement and three parts of sand, when the oil added does not exceed ten per cent of the weight of the cement used. The comprehensive strength of mortar and of concrete suffers slightly with the addition of oil, although when ten per cent of oil is added the decrease in strength is not serious. Concrete mixed with oil requires a period of time about 50 per cent longer to set hard than does plain concrete, but the increase in strength is nearly as rapid in the oil-mixed material as in the plain concrete. Concrete and mortar containing oil admixtures are almost perfectly non-absorbent of water, and so they are excellent materials to use in damp-proof construction. Under pressure, oil-mixed mortar is very efficient in resisting the permeation of water. Laboratory tests show that oil-mixed concrete is just as tough and stiff as plain concrete, and furthermore its elastic behavior within working limits of stress is identical with that of plain concrete. The bond or grip of oil concrete to steel reinforcement is much decreased when plain bars are used. Deformed bars, however, and wire mesh or expanded metal will reinforce this material with practically the same efficiency as in ordinary concrete.

Detecting Icebergs and Land at Sea

IN a discourse delivered at the Royal Institution after the "Titanic" went down, Prof. Howard T. Barnes, of McGill University, described some recent experiments with the microthermometer in the detection of icebergs.

In studying the effect of ice on the temperature of the St. Lawrence River, he found that the ordinary thermometer was useless, and that only through the use of exceedingly delicate electrical instruments can temperature changes be observed. To test the influence of an iceberg on the water temperature he devised a practical form of electrical resistance thermometer, capable of recording thousandths of a degree of temperature, and called a microthermometer. The thermometer coil is composed of a large size iron wire, silk covered, wound between concentric cylinders of copper. The connecting wires pass from a cable to the observing room, where a recorder gives the temperature curve and variations on a chart. The relay galvanometer is of special design, to be independent of vibration, and is exceedingly strong and quite portable.

This instrument was successfully tested in Hudson's Bay in 1910. It was found that as the ship (a Canadian government hydrographic survey boat) drew near a berg, a rise of temperature took place first, followed by a rapid fall. The effect was clearly shown on the microthermometer, but would have been missed entirely on an ordinary thermometer. Prof. Barnes calls this peculiar rise and fall of the temperature "the iceberg effect." It seems to be characteristic and easily distinguished from the small oscillations of temperature in the open sea. The rise is caused by the floating of fresh water from the berg, which water starts colder than the sea and gradually becomes warmer as the distance from the berg increases. At the fringe of this fresh water the temperature is actually higher than the sea temperature, owing to the absorption of the sun's heat. In the open sea, the warming of the sea by the sun is offset by the vertical circulation, but in the fresh and lighter water this is impossible.

During a trip from Halifax to Bristol, Prof. Barnes obtained a record of the sea temperature across the Atlantic. His instrument was placed in the circulating water drawn in by the pumps. The iceberg effect was obtained even in the water drawn from a depth of sixteen feet below the surface.

One of the most interesting results obtained with the microthermometer was the effect of land on the temperature of the sea. Whenever a vessel sails in toward the coast line the temperature is found to fall one or two degrees.

In passing over the great walls separating the shallower water about 400 miles west of the Irish Sea, Prof. Barnes found that the temperature rose sharply to a peak 1½ degrees warmer than the surrounding sea, and immediately fell again, a phenomenon possibly due to the presence of a vertical current of warm water along this wall.

A solution of the iceberg problem seems near at hand, but the greater value of a means of locating land cannot be overlooked. An exceedingly sensitive self-recording instrument, such has Prof. Barnes' microthermometer, is essential. The conflicting experiences of North Atlantic sea captains alone testify to the uselessness of individual observations. Prof. Barnes points out that it is to a knowledge of the rate and characteristics of the temperature variation in the sea, rather than to the actual temperature itself, that we must look for means by which the safety of navigation may be increased.

Dr. Wiley Defends the Bureau of Chemistry

To the Editor of the SCIENTIFIC AMERICAN:

I was surprised, and I must say indignant, at the tenor of your editorial of March 30th, 1912, in which you spoke in such a disparaging way of the young men and women who have been my assistants in the Bureau of Chemistry. As far as I am personally concerned, I never take umbrage at any kind of criticism any more than I become intoxicated with words of praise. No one realizes more keenly than I my own shortcomings and inefficiencies. I have one consolation, however, in this, that so far as I can recall, in all of the errors I may have made, I never have made one to the detriment of a consumer.

The aspersion on the ability and character of my assistants, however, I do not think should pass without a word of protest. Every person in the Bureau of Chemistry, with two minor exceptions, has received his appointment after a rigid examination by the Civil Service Commission. The total number of chemists employed in the Bureau of Chemistry at the time I resigned my position as chief was 189, of whom 106 were employed in Washington and 83 in the laboratories outside of Washington. Of this number 187 were graduates of colleges or universities. The 187 together hold 286 degrees. There are 131 B.S., 41 M.S., 39 B.A., 16 M.A., 26 Ph.D., 12 M.D., and 21 holding other degrees, making altogether 286 degrees held by 187 graduates.

These degrees are from colleges and universities in all parts of this country and in Europe. There are two from Boston University, two from Brooklyn Polytechnic Institute, five from the University of California, four from Clark University, three from the Cincinnati University, nine from Columbia, fourteen from Cornell, twenty-nine from George Washington, eight from Harvard, fifteen from the University of Illinois, two from Johns Hopkins, three from the University of Kansas, four from the Kentucky State University, seven from the Maryland Agricultural College, two from Massachusetts Agricultural College, thirteen from the Massachusetts Institute of Technology, twelve from the University of Michigan, three from the Agricultural College of Michigan, two from the University of Minnesota, thirteen from the University of Ohio, three from the Agricultural College of Oklahoma, two from Pennsylvania State College, ten from the University of Pennsylvania, six from Purdue University, four from Princeton, two from Stanford, three from Tufts, nine from the Virginia Polytechnic, two from the University of Virginia, six from Wisconsin, ten from the Worcester Polytechnic, eleven from Yale, one from the University of Halle, one from the University of Erlangen, two from the University of Göttingen, and three from the University of Heidelberg.

In addition to these, the Inspectors of the Bureau, who are not expected to be college men, are largely the holders of college degrees. Of the forty inspectors, twenty-seven are graduates of colleges.

In order that you may have an accurate idea of the nature of the examinations passed by the chemists entering the Bureau, I addressed a letter of inquiry to Commissioner Black of the Civil Service Commission, and inclose a copy thereof and of his reply. It shows the fundamental training received by the men of the Bureau of Chemistry, and the conditions under which they entered the Bureau.

In regard to the training in the Bureau itself and the work done, I would say that to a large extent, the field of food and drug chemistry being comparatively new and so extensive, we developed, in a way, a training school for food chemists, and our chief difficulty in maintaining the efficiency of the Bureau was that the work of the men was so valuable and so widely known, that they were continually taken away from us by commercial firms, who paid larger salaries than we could in the Government. This can hardly be considered an argument against the efficiency and training of the men engaged in the work, inasmuch as no one will contend that commercial interests are in the habit of employing, at high salaries, men who are not expert in their specific lines.

I doubt if you can find a more capable, more devoted, and more loyal body of college graduates, of the same number, anywhere in the United States. I feel certain that you must have made the statements you did under a misapprehension of the facts, and I sincerely hope that you will take occasion to correct the impression which your editorial has undoubtedly made.

Washington, D. C. H. W. WILEY.

[Dr. Wiley mistakes an academic degree for scientific efficiency. Whether or not the employees of the Bureau of Chemistry passed Civil Service examinations or graduated from institutions of learning is beside the point. We are concerned only with the effective administration of the Pure Food and Drugs Act, in securing the passage of which Dr. Wiley performed a conspicuous public service.

Dr. Wiley states that so far as he can recall he never made a decision to the detriment of a consumer. We would refresh his memory by citing a decision of his which was published fully in the Washington *Post*, and which permitted the use of lead in baking powder. Lead is a poison cumulative in its effect. Surely this was not in the interest of the consumer.

The mere existence of the Referee Board, appointed by President Roosevelt and composed of men of the highest scientific standing, speaks for itself. That board was created for the sole purpose of checking up the work of the Bureau of Chemistry. It has cost this country hundreds of thousands of dollars. To be sure, the idea has been spread abroad that the Referee Board is the tool of food and drug adulterators; that its existence is a menace to the public. On questions of scientific fact, such men as its chairman, Dr. Ira Remsen, are not easily fooled. Nor may one accuse them of corruption without impunity and without incurring a justified indignant protest from every scientific man. So long as the Referee Board is required to continue its critical examination of the Bureau of Chemistry's doings, so long must the Bureau of Chemistry be regarded as scientifically unfit for the task of prosecuting food adulterators.

As an example of the inefficiency of the Bureau of Chemistry we have only to cite the benzoate of soda studies. The important question of the effect of sodium benzoate was intrusted to a medical student who had not even a degree of M. D. Totally inexperienced, totally unfit for this important task, is it any wonder that his results were repudiated by such experienced and respected scientists as Lehmann, the distinguished hygienic authority of Würzburg University? Is it any wonder that President Roosevelt found it necessary to appoint a board which would conduct investigations with scientific accuracy to determine the effect of benzoate of soda? And is it any wonder that the findings of an incompetent medical student should have been reversed?

The Pure Food and Drugs Act is one of the most important pieces of legislation ever passed in this country. That it should be administered by men whose scientific incompetence is a matter of common knowledge is unfortunate for the consumers whom Dr. Wiley states he has always sought to protect.—EDITOR.]

The Scientific Feet of the Bureau of Chemistry

To the Editor of the SCIENTIFIC AMERICAN:

I was interested in reading in your August 3d issue an editorial with the caption "Wanted—A Chief for the Bureau of Chemistry."

The article reads, in part: "Months have now elapsed since Dr. Wiley resigned as chief of the Bureau of Chemistry. That no successor has as yet been appointed may be attributed to the fact that it is no easy task to induce a scientist of commanding position and personality to accept an annual salary far less than the sum which he could earn in a year in private practice. Moreover, the conditions under which work is now carried on in the Bureau of Chemistry would be intolerable to any really scientific man."

Your statement that it is no easy task, etc., is absolutely correct, and it is on this account that the Referee Board was established—a Board composed of scientific experts whose qualifications were such that any investigations conducted by the Board would be recognized in the scientific world as well and faithfully done.

In reference to the conditions existing in the Bureau of Chemistry, I beg to say that there is less friction there now than there has been for some time, as the work is being done harmoniously.

You say, "Selfish manufacturers are bound to do all in their power to make his official life as unbearable as possible, and the spirits that now dominate the work done by the Bureau of Chemistry in passing upon the legality or illegality of the doings of the food and drug manufacturers would hardly be in sympathy with a real scientific chief."

In reference to the above assertion I beg to say that it is the manufacturers who are desirous of having experiments conducted by a truly scientific board.

You also say in part "As matters now stand, the Bureau of Chemistry has the lamentable distinction of being the only department of the Government that cannot stand on its own scientific feet, and that requires scientific supervision by another body."

In reference to the above, I beg to say that the Bureau of Chemistry never had any "scientific feet to stand on."

You also say, "At present wealthy dishonest food manufacturers find it no difficult task to escape the punishment they so richly deserve. Opposed by well meaning but incompetent employees of the Bureau of Chemistry, they find it no difficult matter in court to offset their unscientific evidence by expert testimony, which can be bought at a market price, and which is at least as good as the evidence offered by the Government."

In reference to the above statement, I beg to say that the judgments secured against various so-called "wealthy dishonest food manufacturers," up to August 3d, 1912, numbered 1,550.

Dr. Wiley, in his report on the Committee of Expenditures in the Department of Agriculture, 1910, when he was asked by the chairman, "Do you find difficulty in keeping bright young men in the department at the present time?" said: "That is the great difficulty. As soon as a young man becomes noted for his work he is in great demand, not only in other bureaus and other branches of the public service, but he is in great demand for college and technical work outside. I think the Bureau of Chemistry has lost a larger percentage of its good men than almost any other Bureau in the department. We are losing them constantly."

It was disclosed, during the Coca-cola case, that Dr. Wiley refused to testify, saying he "could not qualify as a chemist, a pharmacologist, a toxicologist, a physiologist, a physiological chemist, or a doctor of medicine either to his own satisfaction or to the satisfaction of the Government."

The above clearly demonstrates that the so-called chief of the Bureau of Chemistry could not qualify as a chemist, and that he was unable to retain good men in his employ, consequently, when truly scientific questions arose they were referred to a board composed of the best scientists obtainable in the United States.

The above are facts, and as the SCIENTIFIC AMERICAN is desirous of giving its readers scientific facts, I trust you will give them an opportunity to peruse the above.

New York, N. Y. H. L. HARRIS.

The Electric Niagara

To the Editor of the SCIENTIFIC AMERICAN:

The issue of June 29th discusses the "Electric Niagara" in France. It occurred to me when reading this article that the French may explain their procedure in such experiments as those performed by Sir J. J. Thomson and others on the effect of potential on cloud formation. Vapor seems to have a tendency to congeal if there are small particles present which form a nucleus. Such nuclei result in diminution of vapor tension and consequent cloud formation. Electric charges seem to form nuclei or accelerate cloud formation, but to my recollection the condition is a critical one.

Rain drops and hail stones require nuclei; and perhaps the French preventive methods, while they are not large enough to handle all the electricity that nature stores, may be supposed to make enough trouble to prevent the critical condition and thus prevent the formation of the starting nuclei.

Cleveland, O. J. C. BOERTLEIN.

[It is quite true that free electrons, however produced, serve, under certain conditions, as nuclei about which water vapor may condense into droplets, but the conditions are so unusual that it seems impossible for them to take place in the open atmosphere. Even the negative electron, which is a much more effective nucleus for condensation of water vapor than is the positive electron, requires (*a*) that the air be free from all dust, and (*b*) that the water vapor present shall produce at least a fourfold supersaturation. But as dust, according to innumerable observations, is always present in the atmosphere, it follows that supersaturation is impossible in the open, and therefore that no amount of ionization can materially affect either the time or amount of rainfall, hail, snow or any other form of precipitation.

From experiments and observations begun by Simpson in India, and continued by others in various countries, it is practically certain that the electricity of thunder storms, whether accompanied by hail or otherwise, is only a by-product of the storm itself and in no sense its cause. Hence to modify it either in kind or amount would be to modify only one of the things which the storm produces and not that which produces the storm.—EDITOR.]

When the Poles Attract Each Other

To the Editor of the SCIENTIFIC AMERICAN:

C. C. Kiplinger, in the issue of March 16th, cites experiments to prove "like poles attract each other." Unfortunately, it seems as though such things as "magnetic rounds" and other luxuries have ousted the old "Filings" experiments from the board. Had he tested with filings he would have found the true cause, which is a very old phenomenon, that of local "reversal of polarity," the larger magnet causing a temporary reversal in the end of the smaller, which then acts as a piece of plain iron or steel. If a steel magnet be used, and then tested, after separation, by filings, it will be found that "consequent poles" have been produced. With the electro-magnet these disappear immediately on separation. I would like to know what he means by "similarity of magnetic and pressure phenomena." HAL MCKAIL.

Kalgan River, West Australia.

Making Models of the Magnetic Field

Fixing the Iron Filings With Plaster of Paris

By Nathan C. Johnson

THE mapping of the magnetic field of force by means of iron filings sprinkled over a glass plate, beneath which is a magnet, is a very old experiment. Faraday was perhaps the first to perform it; and his sketch of the field of force between two parallel conductors as revealed in this way is the earliest record we have of this phenomenon.

Since then, however, the experiment has been performed times without number; but its usefulness has been limited by reason of the decoherence of the filings with the loss of their form as soon as the exciting force was removed, or any unusual conditions of mechanical shock were introduced. Further, only a two-dimension map of the field of force was produced; and although it was known very soon that under normal conditions the field was of equal intensity on all sides of a central line through the poles, yet we have heretofore lacked more than transient ocular proof of this fact.

With a view to overcoming these difficulties and of determining both the form and the intensity of the field under varying conditions of polar form in such manner that the results could be studied at leisure, the experiment herein described was devised. Briefly, it consists in using a mixture of iron filings and plaster of Paris made into a paste with water and sifting this paste over the field area through a medium-mesh sieve. As the iron is carried in suspension in the paste, the mixture is attracted by the poles and the intervening stressed space in proportion to the magnetic intensity, with the result that when the mixture has hardened, due to the setting of the plaster, a relief map, or a three-dimension model of the field of force, is obtained. Photographs of models made in this manner are shown herewith.

Fig. 1 shows a three-dimension map of the field of force between the poles of a powerful electro-magnet. The magnet had square poles, but the effect of this form is not noticeable, due to the intensity of the field employed. In making this map, the procedure outlined above was followed, a glass plate being placed over the poles of the magnet and the paste of plaster and iron being sifted over the plate through a sieve. As before explained, the paste is attracted away from the natural line of fall into the lines of passage of the magnetic flux; and the more intense the field in any locality, the greater the quantity of material at that portion in the resultant map. Therefore, the elevations of the different portions show approximately the intensity of the force at that point; and the direction and inclination of the spines or points rising from the surface also indicate the form and direction of the air lines which were not intense enough beyond a short distance from the pole to hold the material in suspension. In Fig. 2 is shown a profile view of this map, which makes the relief feature more distinct.

Of course the work of applying the paste has to be done very quickly; and the paste must be of just the right composition and consistency to secure good results. Repeated failures are almost sure to be the price of the first success; but once the knack is learned, the procedure will be found easy and the results very instructive. It should also be added that an additional value is given these models by the distinctness and beauty of their color, due to the rusting of the iron, which brings out the lines of force in excellent contrast to the white plaster; and in the map under consideration, a further value is conferred by the reverse side, that which was next the glass plate, having an unusually distinct and accurate force map in two dimensions showing on its surface. This was not photographed because the figure is so well known as not to warrant reproduction.

Fig. 3 shows the field of force of a short solenoid without a core. The making of this model was a very difficult piece of work, due both to the difficulty of obtaining a field intense enough to form the paste properly without undue heating of the coil, and to the necessity of sawing the coil in half afterward without injury to the finer spines of the model. It is to be regretted that some of these have been lost, but enough remain to show the field well. The author hopes in the near future to carry out this work further and to investigate by this same means the leakage in solenoids and the field of force when using different forms of plungers.

By various methods we have long ago determined the effect of various shapes of pole pieces on the attractive power of magnets. Perhaps the first important researches in this regard were made by Dr. Julius Dub in 1850, an account of which is given in his book "Elektromagnetismus." His method of procedure was to have pole pieces of various forms and dimensions which could be screwed upon the core of an electro-

Fig. 2.—Profile of the field of force between the two poles of a magnet.

magnet. Then, with a given excitation of the magnet, he determined the attractive power of the different pole faces by noting the deflection of a magnetised needle hung some distance away by a bifilar suspension. Sturgeon and Count du Moncel also investigated these phenomena, adding to the investigations and conclusions of Dub a research on the leakage of flux with the different pole pieces. At about the same time, Von Kolke investigated flux distribution over different polar forms, and by using a small steel ball, suspended from a spring balance, he measured the pull on the ball over different portions of the polar area. The results of these pioneers have since been substantially confirmed by later investigators, using more refined methods; but it may be interesting for us to prove these results visually by means of the plaster and the iron models.

Fig. 4 shows the field of force over a large flat pole piece. The directions of the lines of force are very well shown in this model, as well as the intensity of the force, showing the great energy at the edges and the relatively small intensity at the center of the pole. This is as we would expect, for from the edges, the lines have a shorter path back to the opposite pole than they have from the center, so that there is greater magnetic density at the edges. A curious optical illusion may also be observed in connection with this photograph. If it is turned upside-down, the perspective of the photograph appears far different from that of the proper position.

Fig. 5 shows the effect of a small flat pole having an air return. By this latter is meant that the opposite pole of the magnet is a considerable distance away, and that the magnetic circuit is completed through the air, with no nearby iron return circuit to build up the intensity of the field. We see from this model that with such a pole, there is a considerable concentration of the force lines at the edge, with resultant spreading. Compared with the intensity of the center of the pole, as evidenced by the length of the spines, the intensity at the sides is much greater.

Fig. 6 shows an exaggerated case of the same kind. In this, the pole face is twice the diameter of that in the preceding, and we have a corresponding increase in concentration at the edges as evidenced by the radiation, and a very noticeable diminution of intensity at the center. It should be understood that in making

Fig. 3.—Field of force of short solenoid without core.

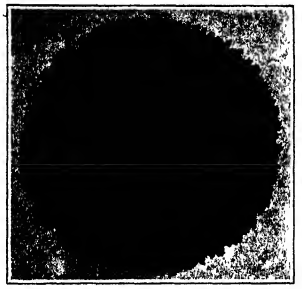

Fig. 4.—Formation over large, flat pole piece.

itself. After hardening somewhat, it was split open to show the interior structure, which should give us the force distribution over the polar face, as well as the field intensity and form. That this result has been accomplished is evident from inspection It is at once seen that the conical pole has the greater concentration of the two, with extreme density of flux from the point; while the rounded pole shows less concentration of the conical pole. The bending over of the lines of force emanating from the flat pole can be very clearly seen in this figure.

Fig. 11 shows the enlarged flat pole as contrasted with the conical pole. This model became too hard to split down the middle, but the interior is hollow for a third of the length from the flat pole, except at the edges, where the material is very dense and converges sharply toward the center. As the quantity of iron in this model is considerable, the lack of radiating spines from the edge of the flat pole may be accounted for by the formation of a magnetic short circuit through the model.

That there are certain defects inherent in these models, and in this method of mapping the magnetic flux, the author recognizes; but they are submitted in the hope that by their use some information may be gained that may eventually lead to a better understanding of some at present puzzling phenomena

Insects and Formol

IT is a matter of some surprise that insects can live in such a powerful antiseptic liquid as *formol*, which is much used in keeping anatomical preparations precisely because it kills the tissues rapidly. A German scientist, M. Schultze, states that flies of the Drosophila genus resist the action of formol in a striking way, and he observes other remarkable cases, for instance hydrocyanic (prussic) acid vapors are exceedingly poisonous and will kill moths at once, but he finds that the zygenes are able to live in it, and even to develop. Jensen states that although the liquid in the pitchers of the nepenthe plant attacks and digests insects, he finds that three culicides will live in it unharmed, and they are protected against the digestive action by an anti-ferment which they secrete Prof Korschelt saw that larvæ of the common fly, when kept in a 2 per cent solution of chromic acid, could be transformed into pupæ and also into winged flies Another German scientist, Prof. Schultze, received bottles from east Africa containing anatomical specimens preserved in formol, and he found a great number of larvæ and pupæ of the *Drosophila rubrostriata*. Fearing that they would attack the specimens, he poured in pure formol, but even this did not kill them Other Drosophila are found to live in liquids which seem unfavorable for development of life, for instance, the *Dr. funebris* and others are found wherever there are substances in acid fermentation, such as in fruits, vinegar or beer They lay their eggs here, and the larvæ find sufficient food, this consisting of spores, bacteria and fermented matter which appear at the surface of fermenting liquids The *Dr aceti* lives in apples or apricots which are in putrefaction, and the *Dr pallipes* lives in the larva state in the sap which flows from cut places in the elm tree Other unusual cases might be mentioned

Fig. 5.—Small flat pole with air return.

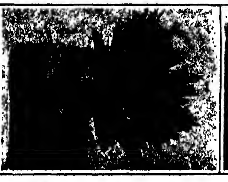

Fig. 6.—Enlarged flat pole with air return.

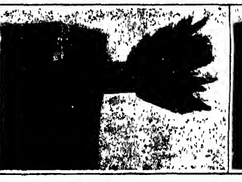

Fig. 7.—Rounded pole face with air return.

Fig. 8.—Conical pole face with air return.

these models, the same procedure was followed as in making Fig. 1; so that they virtually have made themselves, only so much of the material as we picked up by the pole itself being in the model. For this reason, their form may be considered a reasonably accurate representation of the magnetic field.

In Fig. 7 is shown a rounded pole face of small diameter. It will be seen that this has great intensity at the center and less at the sides, with only a slight tendency to radiate outwardly from the sides. This corresponds closely with what we know in regard to the effect of rounded-ended poles for electromagnets.

Fig. 8 shows a conical pole, having, as before, an air return. The extreme concentration of this form of pole is well shown by the length of the center spines and the close bunching of the whole mass around the center.

To confirm the last two results and to contrast them with each other, as well as to show the form of an intense field between two such poles, let us refer to Fig. 9. This model was formed in the same manner as were all the others, so that it, too, may be said to have built tration at the middle and a greater tendency to radiate from the sides.

In Fig. 10 the contrast between the poles is still more marked. In this case we have a small flat and a conical pole, the model having been split open as before. It will be noticed that the structure is less dense in the center than was that formed by the rounded pole, while the tendency to radiate from the edges is greater, especially so in contrast to the con

A Motor-driven "Mauretania"

BASING its estimate on the amount of fuel required by the "Selandia" of 2,500 horse-power, and assuming a consumption of 11½ tons of oil per day, the *Engineer* estimates that the "Mauretania" would require 313 tons of fuel per day, or 1,487 tons for a run across the Atlantic It is estimated that if the "Mauretania" had a double hull, with one foot between the two skins, she would have storage space in her sides of about 56,240 cubic feet, which would be sufficient to contain the oil necessary to carry her across the Atlantic.

Side of the shield.

To the left and right respectively are the cutting ring and building hood. Hydraulic rams in the center space, which was originally of wood.

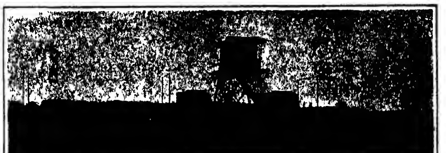
Excavating the Beach Shield

DURING the excavation in the month of August last of lower Broadway under the supervision of the Public Service Commission of New York city for the building of the new Broadway and Lexington Avenue four-track subway, the engineers had to remove the smaller tunnel, 10 feet exterior diameter, built in 1869, located under the center of Broadway, opposite City Hall Park, and extending from the south side of Murray Street to the southwest corner of Warren Street on the north.

This tunnel had been constructed under the street at that early period without disturbing the surface or the traffic over head, as described in the SCIENTIFIC AMERICAN of March 5th, 1870, by means of the Beach hydraulically propelled cylindrical shaped shield, built of wood and iron, the exterior diameter of which was of the same dimensions as the trailing tunnel of tube, or about 10 feet

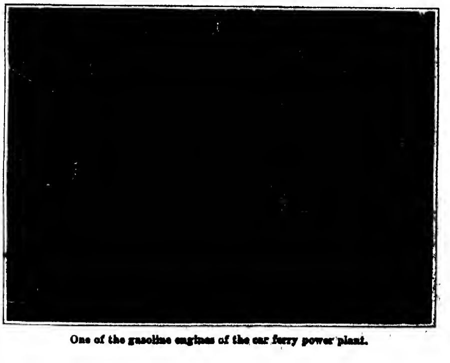
It was the invention of Mr. Alfred E. Beach, one of the original proprietors and editors of the SCIENTIFIC AMERICAN. Upon the request of Mr. Alfred E. Beach's son, Mr Frederick C Beach, now also one of the owners of the SCIENTIFIC AMERICAN, and the courtesy of the officials of the Public Service Commission, the contracting company was asked to refrain from demolishing the shield after it was dug out, with a view of its removal, preservation and restoration as a historical relic, it being the first machine of its kind to operate in tunnel construction work in New York city and the forerunner of all the great shields used in the construction of the mammoth electric railway tubes now under the rivers about this great city.

An inspection of the shield from the exterior as it lay partly imbedded in the sand, by Mr F C Beach (who actively supervised the operation of it in 1869), disclosed the fact that in all these 43 years the iron and brass work, including the thin hood of iron on the rear, had remained in pretty good condition, but the wood staves between the front cutting ring and rear ring carrying the hydraulic rams and the cross front wood shelves had entirely disappeared and rotted away. The flashlight photograph, with Mr Beach standing near the cutting edge, shows the one half of the front cutting ring with projections on its interior surface, to which was secured by bolts the ends of the thick transverse shelves for the purpose of preventing the inflow of loose sand. In the center, is observed the timbers used by the contractors to support the present street planking over head as well as the electric street railway. The side view shows the side of the front cutting ring connected by inch stay rods to the rear of the hood-ram supporting ring, and between these rods at equal distances will be observed the cylinder ends of the hydraulic rams with bent tubing on the rear, which connected with the main supply pipes from the hydraulic pump. This was operated by manual power. The long thin cylindrical hood is attached to the rear piston ring and extends back from it some two feet or more. The pistons within the rams are forced out by water pressure against the completed tunnel, built up within the hood, pushing the shield forward through the sand to the extent of the hood; then a new layer of masonry is built and the process repeated. By this method only the quantity of earth is removed that is required for the tunnel to occupy.



A full side view of the all-steel interurban car ferry "Henderson."

This car ferry has a capacity of two electric passenger cars, a speed of 8 miles per hour, and is operated by gasoline power.



One of the gasoline engines of the car ferry power plant.

Car Ferry Service Across the Ohio River

AN experiment in interurban railroad practice which has been worked out at Henderson, Ky., demonstrates the efficiency of gasoline power for use on car ferry work.

The "Henderson" is the first interurban car ferry ever built, and the first large car ferry operated by gasoline power. She is all steel; length over all, 120 feet; beam over all, 34½ feet; beam at water line, 25 feet. Her displacement when light is 88 tons, and loaded with two electric interurban cars, 150 tons.

Her power plant is two 54 horse-power "Buffalo" heavy duty gasoline engines, seven-inch bore and nine-inch stroke, with a normal speed of 350 revolutions per minute. Each engine drives one side paddle wheel, but there is additional gearing by which one engine can operate both wheels if desired. The motors drive the wheel shafts through large bevel gears at a ratio of 10 to 1. The side paddle wheels are 10 feet in diameter, three feet wide and have 20 blades 18 inches deep.

Economy was one reason why gasoline power was chosen for use on the "Henderson." While it takes her only six minutes to cross the Ohio River with the current, and an additional two minutes when going against the current, the "Henderson" is called upon to make only one round trip every hour. This means that most of the time she is standing idle at one side of the river or the other, waiting for her cars to arrive. With a steam plant this would mean a great waste, for coal would be consumed all the time the boat was at dock, but with gasoline engines, when the boat stops, the cost stops, there is no steam to keep up.

An Electric Harp

By [illegible] Williamson, Jr.

BEING possessed of a three-bar auto-harp, of which the bar mechanism had been accidentally broken, it occurred to me that it might be arranged to be played by electric power.

My first intention was to have pickers for the strings as in a regular harp, but this scheme was abandoned, as too complicated, an arrangement for striking blows upon the strings, being substituted. Some experiments showed that the simplest plan was to use solenoids, that is, magnet coils with movable iron cores. How this was managed and the apparatus constructed, is shown in the accompanying illustrations.

Upon the harp *A* (Fig. 1) were screwed two upright side pieces *B* and *B'* with foot pieces *C* and *C'* to support the instrument in inverted position for play-

The electric harp in operation. A solenoid shown in the insert.

ing. Three strips, *D*, *G*, and *I*, of 5/8th stuff, 1½ inches wide, were then cut out. The strip *D* was laid across the 21 strings of the harp, between the two uprights, and carefully marked where the strings crossed it. These marks were extended to the 1½-inch side, crossing two parallel lines drawn lengthwise on the strip, ½ an inch apart. A light mark was then made in the wood, with a center punch, at alternate points where the cross lines joined the parallel lines, "staggering" them, as it is called. At each mark, a 3/16-inch hole was then drilled perpendicularly through the wood, using a twist drill.

The solenoid coils were now wound upon 21 pieces of 3/16-inch thin glass tube, 2 inches long, the glass being nicked with a file and broken between the fingers. The winding was done thus: A bit of ⅛-inch brass rod 3 inches long was clamped in a vise, and one of the tubes slid upon it. A wooden crank was then forced temporarily on the glass, and the latter wound with four layers of No. 24 enameled copper wire, in a coil 1½ inches long. The terminals were twisted together and the ends of the coils shellacked to prevent their slipping.

The free ends of the tubes were then set in the drilled holes in the wooden strip *D*, and glued securely, after which the strip was secured between the uprights, in such a position, that the ends of the solenoid tubes E^1, E^2, etc., were one half inch from the harp strings, which show in the figure as a row of dots. One terminal of each coil was then scraped free of enamel and soldered to a common return wire *F*, terminating in a screw and washer on one of the side pieces, for a battery connection.

The strip *G* was then screwed between the uprights, close to, and at right angles with, the strip *D*. It was drilled to receive 21 round head No. 6 brass screws, one inch long, provided with washers. The screws were set in opposite sides of the strip, alternately, similar

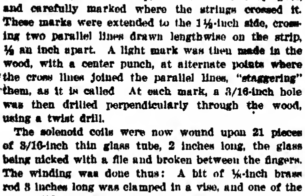


Fig. 1.—Front view of solenoids.

to the solenoids. The iron cores for the magnets were made from 3-inch wire nails of a size to just slip easily into the tubes. The heads were cut off, and both ends were filed flat, reducing the length to 2½ inches. They were then set in place in the tubes, as shown at H^1, H^2, etc., and the strip *I* upon which they were to rest, was secured between the supports, 2 inches below the strip *D*, so that ½ inch of the core remained in the tubes. The upper face of the strip *I* was padded with a four-fold thickness of canton flannel, to reduce the noise of the dropping cores. A similar strip of flannel (*V*) was glued to the face of the harp, opposite the solenoids, to cut down the reverberation of the strings.

The keyboard and music roll attachment, shown in Fig. 3, consisted of a base board *J*, 13 inches long with upright sides *K*, *K'*, 5 inches high. The rollers, *L*, *L'*, were made of 12-inch lengths of 2-inch curtain pole, with 2¼-inch heads *M*, *M'*, etc., turned from cigar box wood. They were pivotted at one end, on wire nails, driven into the centers; and revolving in holes drilled in the side piece. In the other ends were forced 2-inch cranks of 3/16-inch round brass rod *N*, N^1, revolving in open slots in the side piece to allow the rollers to be easily removed. The slots were covered with small brass strips which could be turned aside to release the

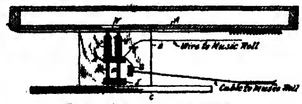

Fig. 2.—End view of solenoids.

rolls. A cross strip, marked *O*, was fastened to the top of the side pieces, just back of the front roller, and to this was secured a strip (*P*) of 1/16-inch brass 3/8-inch wide provided at one end with a screw and washer for the battery connection.

Half an inch back of strip *O* was placed a second cross-piece *Q*, of the same size as the former, but raised ½ inch above it, on small blocks. One end of strip *Q* was hinged to the block and the other held down by the latch *S*. To the narrow edge of this strip were screwed 22 strips of light spring brass R^1, R^2, etc., 1¼ inches long and tapering from ¼ inch wide at the large end to 1/16 inch at the small end. The strips were clamped together in a vise, and drilled through the wide end in one operation with a hole large enough to take a No. 6 screw. The extreme tips of the narrow end were turned up slightly to avoid catching in the music roll, and the whole set fastened by screws to the strip *Q* in such position that the small ends pressed firmly upon the cross-strip *P*, and were spaced just ½ inch apart.

The paper music was made from a strip of heavy wrapping paper, about 6 feet long by 12 inches wide. One end was cut V-shaped, the point being tacked to the center of the front roller, which was then turned over a couple of times to hold the paper firmly. The paper was then wound forward under the springs, and the notes and chords marked in pencil in a line with the corresponding springs. The bar *Q* was then thrown back out of the way and a strip of wood, sawed across the grain, was set temporarily beneath the paper at this point. This wood was 12 inches wide and 5¼ inches high, and was used as a support upon which the holes were punched in the paper at each pencil mark, using a hollow steel punch of 3/8 inch diameter. The end grain of the wood allowed the punch to sink in, making a clean, round hole. Perforation for successive notes were spaced ¼ inch apart. The harp and keyboard were connected with No. 24 enameled wire, as the distance between them was only about 18 inches. For a longer distance No. 18 or 20 wire would be required. A wire was connected to screw No. 1 on the cross-piece *D*, Fig. 1, and the other end to the screw on spring No. 1 of the keyboard. No. 2 screw on the harp was joined to spring No. 2 with a second wire, and so on. The wires were then gathered into a cable *U* and taped together as shown. A battery of two or three dry cells was attached, one terminal going to the screw on the common return wire *F* and the other to the screw on the strip *P*.

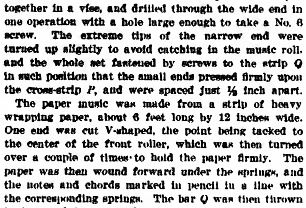

Fig. 3.—Music roll mechanism.

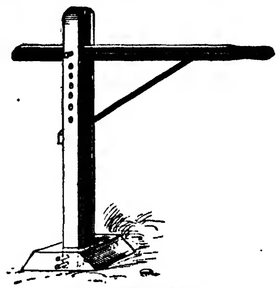
To operate the harp the crank of the front roller was turned to draw the paper forward, and as the perforations in the latter reached the various springs, they dropped down into contact with the strip below, throwing the current into the corresponding solenoids and drawing up the iron cores so that they struck the strings with a clear, sharp blow, dropping instantly as the paper was drawn forward, and the current shut off. The best average speed for the roll was found to be about two longitudinal feet per minute.

A Simple Vehicle Jack

By James H. Armstrong

ONE of the simplest forms of jacks for use in lifting the bodies of wagons or other vehicles is illustrated in the accompanying drawing. The device can readily be made by any amateur and the construction is inexpensive. The uprights of the jack consist of a single length of iron 1¼ by ½ inch, bent double or to hairpin form, with the lower ends secured in a block of wood measuring 2 by 6 inches. The ends of the uprights are fixed into recesses in the block, and are held in place by means of bolts as indicated by dotted lines in the drawing. The lever on which the vehicle



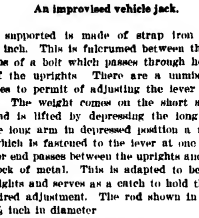
An improvised vehicle jack.

axle is supported is made of strap iron measuring 1 by 3/8 inch. This is fulcrumed between the uprights by means of a bolt which passes through holes in the sides of the uprights. There are a number of such bolt holes to permit of adjusting the lever to various heights. The weight comes on the short arm of the lever and is lifted by depressing the long arm. To hold the long arm in depressed position a rod is provided which is fastened to the lever at one end, while the other end passes between the uprights and is welded to a block of metal. This is adapted to bear against the uprights and serves as a catch to hold the lever at any desired adjustment. The rod shown in the drawing is 3/8 inch in diameter.

Lashing or Seizing Timbers Together

By Albert F. Bishop

TIMBERS from 7 to 10 inches in diameter can be bound together readily with wire about the size of that used in telegraph lines. The end of the wire is turned at right angles and fastened to the timber by a staple. The wire is then wound around the two pieces as tightly as possible from four to six turns. The end of the last turn is bent at right angles and fastened to the other timber by a staple. Now a small pointed bar is inserted in the center of the layers and



Method of lashing timbers together.

the layers are twisted several times as shown in the sketch. The writer believes two pieces could be bound together in this manner as tightly and firmly as the use of bolts could make them. This method requires very few tools and very slight expense for materials. This wrinkle can be applied to telegraph poles, flag staffs, or repairing fence posts, etc.

Healing Broken Machinery by the Electric Flame

By Joseph B. Baker

A BROKEN machine is only the picture of its real self. The machine is all there, but it is useless because of the break in some important part which destroys its strength. Now the unsound part may be healed and so reclaimed by the electric flame. The castings and forgings which make up large and expensive machines sometimes break in ordinary use, or are broken by accident, causing great loss, and delay to the work in which the machine is being used. The simple electric arc welding system, applied in an hour's work or more by a skilled man, makes such broken parts as good as new, no matter how "far gone" the crack, or how extensive the actual, open rupture through the very structure of the part.

For example, the motor shells and gear boxes of electric cars may become cracked by yielding to the fatigue of the metal in the ordinary operation of the car. Cracked motor shells were formerly either sent to the scrap-heap or else repaired by riveting a plate over the break. To send the part to the scrap-heap means practically throwing away an expensive steel casting on which perhaps, a lot of valuable machine work has also been done, and to repair the part by riveting is to fail to restore the original strength and rigidity. The same thing applies to the steel forgings of car-truck frames, parts of printing presses, or the part or forged parts of any good-sized machine. The need is, then, for some means of easily, quickly and inexpensively mending such broken parts.

This need is filled in the electric arc welding process, which can be used on the spot, wherever direct electric current is available, and in a small space ten feet square. Arc welding reclaims the part at an expense which is very small compared with the cost of a whole new part, a cost which does not exceed the expense of the far less effective riveting. The occurrence of a bad crack, or of an actual break in a big, expensive casting or forging is the opportunity of the arc welder to make whole and sound again a piece which had seemed irretrievably ruined. Steel castings cost more than iron castings, and it pays correspondingly better to repair them by the arc welding process. They are just as easily healed as the latter, and it is something worth while to recover a steel casting for example costing \$500 with half a day's work at an expense of a tithe (or less) of the first cost of the piece.

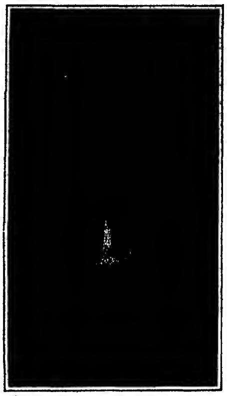
By the use of a direct current of 220 volts or over all castings and forgings except brass, bronze or copper can be repaired by genuinely welding the break, using the arc to soften the metal adjacent to the break and then feeding in a piece of metal of the same or better grade to fill in the break and make the piece integral. If alternating current only is available, it may be transformed into the necessary direct current by the customary apparatus for this purpose, such as the mercury arc rectifier for relatively small work. The process is simple and rapid, but certain precautions are necessary. The operator's only tool is the carbon electrode in its holder, a hand tool with means for protecting the operator's hand and body from the heat of the arc. The head and body are protected by a canvas hood, and the eyes by goggles having several thicknesses of colored glass. The carbon pencil, ½ inch to 1 inch in diameter, according to the size and shape of the work, is made the negative electrode, and the voltage is cut down to about 100 volts at the arc by a suitable adjustable resistance.

When the piece is once set and aligned, and the current turned on, the work proceeds with marvelous rapidity. The searching and penetrating heat of the arc easily softens metal shells of the ordinary thickness found in the structural castings of machinery or in the main or minor moving parts of the same, up to 4 inches; the ½-inch to ¾-inch thickness of a motor shell is quickly brought up to welding temperature necessary for a true union of the parts. If overheated by the intense play of the arc the metal runs like wax, and here is where skill and special manipulation of the powerful tool is required.

It is better of course to apply the welding process to pieces when they are first found to be cracked, or to have a crack starting, from some habitual or repeated stress or an accidental shock, and before they become broken away entirely: "a stitch in time saves nine." In some cases there is opportunity to make the work even better than new by welding upon it strengthening or reinforcing parts.

Mending a broken gear: a difficult job of arc welding. The gear teeth at the break were saved. The alignment had to be maintained exactly during the welding.

A mended break that extended from above the armature bearing to the gear-shaft bearing.



The arc welder at work on a railway motor shell. In practice the arc used is somewhat shorter than in the illustration.

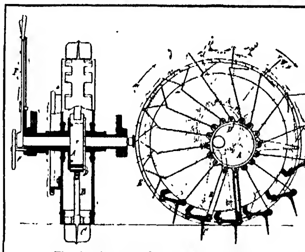


Fig. 1.—Front and side views of traction wheel with retractable blades.

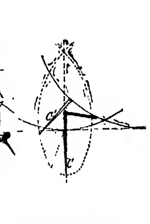

Fig. 2.—Paths of fixed and retractable blades.

The new traction wheel driving a plow through an alfalfa field.

Plowing a rice field; a supreme test for the traction wheel.

A Novel Italian Traction System

MOTOR-DRIVEN agricultural machines operate with difficulty over ground strewn with straw or other material of a slippery nature. In order to give the driving wheels an adequate purchase on the ground they must be made very heavy and must be provided with cleats. This adds a material load for the engines to drive and is entirely unnecessary in the opinion of two Italian inventors who have devised the traction wheel illustrated in the accompanying engraving. In place of cleats the traction wheel is provided with long blades, designed to dig into the ground. Whenever desired the operator may retract these blades, so that the machine can travel over an ordinary road without injury to the road. The construction of this wheel is illustrated to the best advantage in Fig. 1. The axle of the wheel carries an eccentric *A*, on which is mounted a strap connected by rods *B*, with the traction blades *C*. As the traction wheel revolves, the eccentric *A* remains stationary, but the strap *D* must revolve with the wheel and consequently the traction blade must assume the positions shown in the drawing. It will be observed that in the forward half of the wheel the blades project from the periphery of the main wheel rim *E*. The blades are pressed into the ground by the weight of the wheel, but are immediately retracted after passing the point of contact of the wheel with the ground. As the blades are retracted in a vertical direction they do not serve to scoop holes in the ground as would fixed cleats of the same depth. Fig. 2 shows in full line the cut in the ground made by the blade that is retractable, while the dotted lines show the large hole in the ground that would be scooped out by fixed blades projecting from the rim of the traction wheel.

When it is desired to run the traction wheel without projecting the blades into the ground, they may be moved to a different position by operating the lever *F*, so as to throw the eccentric *A* to the position shown by dotted lines in Fig. 1. Then the blades will project from the upper half of the wheel and will be withdrawn in the lower half where the wheel comes in contact with the ground. One of the accompanying illustrations is a photograph of the machine operating through a rice field. Here it is put to an extreme test for the reason that the field is flooded with water, and affords very little purchase for a traction wheel. Another picture shows a plow equipped with a traction wheel of the new type, operating in an alfalfa field. The new type of traction wheel affords an ideal hold on the ground and permits of reducing materially the weight of agricultural machinery. Furthermore, the ability to regu-

the depth to which the blades will sink into the ground and to retract them completely if desired, is a very important advantage.

The Trade-mark as a Business Asset

By W. E. Woodward

THE average business man has only the vaguest notion of the value of a trade-mark. He does not realize that it is very often the connecting link between the producer and the ultimate consumer; that it is a symbol of good will, a tangible asset with a determinable money value; that it must be chosen and applied not in a haphazard way but with a due regard for its psychological effect upon the public. Nor does he realize the importance of complying with the statutory requirements which secure to him a property right in a trade-mark comparable with the property right that an inventor acquires by taking out a patent.

The following is the last of a series of articles, written by a man who is at once a trade-mark, an advertising, and a business expert, a man who has a first hand knowledge of the value of trade-marks and of the correct methods of trade-mark exploitation. The series, which will be eventually published in book form, included discussions, written in business English, of the Federal trade-mark law, analyses of the requirements for registration, the elements of a good trade-mark, and trade-mark promotion.—EDITOR.]

An Ingenious Similarity of a Trade-mark.

—IX.

(*Concluded from page 184, August 31st, 1912.*)

An infringing mark may be so nearly like a well-known and valuable trade-mark that the unwary or careless may be deceived, yet, at the same time, it may be so dissimilar that a show of defense may be made. The National Biscuit Company has prosecuted more than five hundred infringements of its trade-marks. "Uneeda" Biscuit has been imitated by "Ulika," "Uwanta," "Iwanta" and dozens of other specious wordings.

The mark "Yusea" used on incandescent gas mantles, was infringed by "U-C-A." In this case there was no similarity whatever in the appearance of the marks, but evidence was produced to show that "Yusea" was pronounced "You see a," and that in sound the marks were precisely the same. Priority of registration of the "Yusea" mark was proved and the use of "U-C-A" was accordingly enjoined.

The word "Chasseuse" was held by the court to be an infringement of "Chartreuse"—both marks being applied to cordials.

"Grape Nuts," a cereal food, was not infringed by "Grain Hearts." "Old Crow," the name of a whiskey, was not infringed by "Old Jay."

On the other hand "Colonial Dame" used in connection with perfumery, was infringed by "Colonial."

"Chatter-Box," an annual publication for children, was infringed by "Chatter-Book," used as the name of a publication of the same general appearance and purpose.

The Right to Use One's Name and Its Limitations.

A typical case of this kind is that of Royal Baking Powder Company v. Royal (122 Fed., 337-1903; 58 C. C. A., 499-500). An individual by the name of Royal went into the business of manufacturing baking powder. His product was sold in packages of the same general appearance as those containing the product of the Royal Baking Powder Company. The court held that the respondent could use his own name, but "in the least conspicuous manner possible consistent with the right to place his name and address upon the goods made by him."

A similar case is that of Von Faber v. Faber (124 Fed. R., 603). In this case the plantiff, a manufacturer of lead pencils, was the owner of a business founded in 1761. The pencils made by this firm had always been marked "A. W. Faber." The defendant, also named Faber, began to manufacture pencils in the United States, affixing to his product the mark "Faber." The court held that this was an unfair use of his name, and while he had a right to use his own name, yet he must prefix to it "John E," "Eberhard" or "John Eberhard."

The well-known chocolate manufacturers of Dorchester, Mass., Walter Baker & Co., have had to contend with many individuals bearing the name of Baker. In each case the decisions of the court have been to the effect that any Baker has a right to manufacture and sell chocolate, and to use his own name on packages of his product, but his name must be accompanied by some statement or distinguishing mark which will clearly differentiate his product from that of Walter Baker & Co.

In the case of Williams v. Mitchell (106 Fed. R., 168-171) the court said: "One may not use his own name for such purpose when it works a fraud. If he uses a descriptive word, or a geographical name, or his own name, it must be so used as not to deprive others of their rights or to deceive the public, and the name must be accompanied with such indications that the thing manufactured is the work of the one making it as would unmistakably inform the public of the fact."

Casual Resemblance Is No Infringement.

A manufacturer of a lantern known as a "Hurricane" lantern claimed that the name of another lantern, called "Tempest," was an infringement. The court held that while there was a resemblance in the names in the underlying idea, they were so different in appearance and sound that any person of average common sense would not mistake one for the other.

"S. B.," a trade-mark for cough drops, was not infringed by "B. and S."

"Weber," a mark for pianos, was not infringed by "Webster." In this case there is a casual resemblance in appearance in the two words, but no resemblance or very little, in sound.

The Plaintiff Must Come Into Court With Clean Hands.

The courts will not use their power to perpetrate a fraud. A trade-mark conveying a misrepresentation of the composition, character or quality of the goods with which it is used, cannot be protected against infringement.

How Legislators View Patents

THE debate on August 7th in the House of Representatives upon the question of appropriating ten thousand dollars to investigate the Patent Office, developed some interesting statements from different Congressmen. Chairman Oldfield of the Patent Committee said, "the Patent Office has taken in and turned into the Treasury about $7,000,000 more than it has taken out of the Treasury." In speaking of the great corporations, who are said to take men out of the Patent Office, the same gentleman said: "They want men who have started at the bottom in the Patent Office and have worked themselves up to the Commissionership or assistant Commissionership." If they want such a man, we do not recall an instance in which they got one, as ordinarily the force of such companies is recruited from the assistant examiners of the Patent Office.

Congressman Mann said, he thought the salaries in the Patent Office ought to be increased, but asked if Chairman Oldfield did not believe the Government would never be able to compete with salaries offered by outside people. Congressman Bowman remarked: "I have had some business with the Patent Office and the work that they have done for me, has always been efficient." Mr. Bowman also said: "Ease in securing a patent is, I believe, of great advantage to the country," and further "I consider as one of the greatest assets of this country the inventive genius of its people. I do not favor the suggestion of the committee, that there might be a slight advance in Patent Office fees. They should be kept low and every encouragement and assistance given inventors."

Referring to the bill to codify the patent statutes upon which hearings have been had this year, Chairman Oldfield said, "a substitute for that bill will be reported to the House in a few days, but it is not believed that it will be possible to discuss the bill or pass the bill at this session." This appears to settle the question as to any revision of the patent laws at this session of Congress.

In the course of the debate, Chairman Oldfield referring to the compulsory license of the proposed new law, pointed out that it differed from other laws of the kind in that it did not apply to the original inventor, but only to those corporations or persons who acquire patents for the purpose or with the result of stifling competition.

Speaking of the bill about to be introduced, Congressman Lafferty said, as he understood the bill, it would make it a penal offence for the owner of one patent to buy another patent with the intention of restricting or interfering with its manufacture or sale, and Chairman Oldfield replied that such was the intended result.

With reference to the Sherman anti-trust law, Mr. Oldfield announced that a great many of the best patent lawyers in the country to-day, take the position that the law does not apply to patent monopolies, but that the proposed bill will provide that the law shall be applicable to those monopolies created by the accumulation of patents.

Included in the debate was a brief discussion as to the constitutionality of deputizing to a court the fixing of a license fee, Congressman Cooper asking whether such fixing was a judicial function and suggesting that a court cannot fix the rate, but it can decide whether the rate is confiscatory or not. At any rate, Chairman Oldfield said the bill is not to be pressed for passage at this session of Congress.

Notes for Inventors

Four Glass Drawing Patents.—Four patents, numbered from 1,034,445 to 1,034,448, inclusive, have been issued for the inventions of Mark J. Healy of Bradford, Pa. The inventions relate particularly to devices in connection with glass drawing apparatus and to the ring shields and fenders operating in the tanks of such apparatus.

Wanted: An Artificial Bait.—John W. Hurley, is well known among Washington city fishermen, for his skill with the rod and reel. A recent issue of the Washington *Star* says, that Mr. Hurley thinks it about time that some one invented an artificial bait for salt water fish and quotes the veteran angler as saying:

"Peelers make fine bait, and soft crabs are not bad, but usually it is hard to get them at places, where there is a chance to make a good catch. Some of the fishermen laughed at me, when they saw me taking soft crabs from the city for bait, but when they reached the fishing grounds, they were sorry they hadn't invested in some of them in the city."

A Moth-proof Fly Book.—A patent has been granted to F. J. Cooper of San Francisco, Cal., for a fly book which should be of interest to fishermen. The inventor, when he first started out in his career as a fisherman, bought everything that was recommended as needful. A generous assortment of expensive flies formed part of his equipment. He found that the flies lasted just one season. When springtime came he went to his kit and was amazed to find that the moths had cleaned his books of dozens of flies. That inspired the idea of a moth-proof fly book. The result is a book that is moth-proof, in which there is no metal in contact with the hooks, which is dust-proof and damp-proof. A celluloid window on the top of each of the envelopes constituting the leaves, permits the user to see at a glance just what fly he wants. The book is made on the loose-leaf principle and holds twelve to fifty-four dozen flies.

An Electrically Conductive Ink.—Two patents, Nos. 1,034,103 and 1,034,104, have been granted for the inventions of Hyman Eli Goldberg, wherein he provides a visible writing ink having as one of its constituents a good electric conductor so that the ink when applied to the paper by an ordinary writing pen and dried can be used to conduct electricity along the characters thus produced upon the paper.

The Patent Medicine Situation in England.—A committee of the House of Commons has, for some time past, been holding sessions in London for the purpose of investigating the law regarding the sale and advertisement of patent medicines in the United Kingdom.

In the course of the investigation, it has been developed that the sale of such medicines is equivalent to one package per year for every man, woman and child in the country, that as estimated by one witness, the amount of money spent on proprietary medicines in Great Britain alone in one year amounted to $12,166,250 or sufficient to maintain 40,000 hospital or sanatorium beds and that notwithstanding the enormous amounts expended, the solicitor to the customs and excise department stated, in answer to question from the chairman of the committee that there was nothing, in his opinion, in the law as it now stood to prevent any person making up any sort of mixture containing anything except obvious poison, from advertising it as a cure for any disease, and selling it to the public on payment of the stamp duty. He added that probably the police could prosecute if absolute fraud were established, but that it would be exceedingly difficult, in his judgment, to obtain evidence that would insure a successful prosecution.

Legal Notes

Patentability Not Involved in Interference.—The Court of Appeals of the District of Columbia in the interference case of Putnam v Wetmore and Niemann, has held that the question of the patentability of the issue of an interference, will not be considered by the Court of Appeals and says, quoting a number of other cases "In interference cases we do not determine whether either party shall receive a patent. The question presented to us is, conceding there is a patentable invention, which party was the first to invent or discover the same."

Reasonable Doubt as to Similarity.—The Commissioner of Patents, in the case of J. & Riley Carr v. The William Schollhorn Company v. Warren Ax & Tool Company v. Geo. H. Bishop & Co v. Radigan, Rich & Co. v. Draff v E. C. Atkins & Company, has held in a trade-mark case that where there is a reasonable doubt whether there is deceptive similarity between the mark of an applicant and that of a prior registrant, and the consent of the registrant to the registration by the applicant of his mark is secured, that the doubt should be waived in favor of the applicant and his mark registered.

A Decision Affecting Absinth.—The Board of Food and Drug Inspection of the Agricultural Department has issued a decision, No. 147, under the section of the Food and Drugs Act which forbids the importation of any food or drug which is "of a kind forbidden entry into, or forbidden to be sold or restricted in sale in the country in which it is made, or from which it is exported," and also of any food or drug which is "otherwise dangerous to the health of the people of the United States," calling to attention that importations of absinth into the United States, are prohibited, both because they come from countries which forbid or restrict its manufacture and sale, and because these products are injurious to the health of the people of the United States. The decision holds that the Secretary of Agriculture will regard as adulterated under the Food and Drugs Act absinth which, on and after October 1st, 1912, is manufactured or offered for sale in the District of Columbia or the Territories, or shipped in interstate commerce or offered for importation into the United States. The effect of this decision upon trade-mark registration is somewhat problematical, especially as to the marks, should there be any, applied to absinth manufactured in this country and designed for export.

RECENTLY PATENTED INVENTIONS.

These columns are open to all patentees The notices are inserted by special arrangement with the inventors. Terms on application to the Advertising Department of the SCIENTIFIC AMERICAN

Pertaining to Apparel.

BELT BUCKLE.—L. SANDERS, 621 Broadway, New York, N Y A highly important result obtained in this construction is the rigidity between all the parts of the base of the buckle, the arrangement being such that rigid relation is maintained between the means for fastening the buckle to the belt and means for adjustably making connection between the free end of the belt and the front end of the buckle

DRESS.—D ZAVODNIK, 40 Walker St, New York N Y This invention relates particularly to a lady's house dress, and an object is to provide a dress which will be neat in appearance about the waist, avoiding the objection raised to the loose fitting morning dresses, and which will adhere to the waist of the wearer, irrespective as to whether or not corsets are worn

Pertaining to Aviation.

FLYING MACHINE.—T W CAREY, JR, 809 Canal St, New Orléans, La. It is the object of this improvement to provide a flying machine with one or more sets of equilibrium planes and ailerons adapted to counteract the tilting action and to reduce the inverse angle, whereby shorter turns may be accomplished with less danger.

FLYING MACHINE.—C A. HAMILTON, Box 421 Sag Harbor, N Y An object here is to provide a machine of the helicopter type with a plurality of propellers, and means for directing the line of action of said propellers so as to traverse the machine in any direction; also a machine with a plurality of helicopter propellers, with means for throwing into and out of operation any one of the propellers

Of Interest to Farmers.

CRANK HEAD FOR MOWING MACHINES.—L. R. WHITESIDE, R F D No 6, Belleville, Ill. A purpose here is to provide a crank head with a crank pin sleeve having a plurality of pairs of trunnions interchangeable with the pitman, so as to take up the wear and obviate irregularities in the movement of the mechanism, so as to prevent excessive jarring.

Of General Interest.

GASOLENE FILTER.—J. C KLATZL, 45 W 83d St, New York, N Y This invention pertains to a new form of gasolene filter, and an object is the provision of a device of the above indicated character from which the water or other heavy substance will be baffled and precipitated from the gasolene before the latter passes through the screens common to devices of this character From this device the screens may be readily removed and inserted A further object is to provide a device which may be readily cleaned and in which the several parts may be quickly assembled or removed The engraving pictures a vertical sectional view of the filter.

GASOLENE FILTER

FILTER.—E SEAVEY, Manhattan, N Y, N Y This invention relates to a filter for filtering any desired liquid material, such as sugar solution, water or petroleum Means are provided by the invention whereby the sediment and foreign particles filtered out from the liquid can be collected in a catch basin and at suitable intervals removed from the filter

BRACKET FOR CARD HOLDERS.—J A MANSON, 347 W 87th St, Manhattan N Y., N Y In the present patent the improvement has reference to a bracket for pivotally mounting holders for display cards and an object of the invention is to provide a simple inexpensive holder for card plates so that the latter may be readily and quickly dismounted from the bracket.

Hardware and Tools.

RIVET CALKING TOOL.—J WOODWARD, Box 206, Leetonia, Ohio The aim of this inventor is to provide a new rivet calking tool, which is simple in construction and arranged to permit a ready change in the calking hammers and guide for the use of the tool on different forms of rivet or bolt heads, with a view to calk or tighten the rivet or bolt

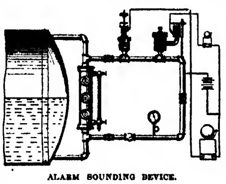
APPARATUS FOR SPLICING ROPES AND CABLES.—H. H. WILSON and H. H. ROSS, Box 877 Nasel, Wash The object of this improvement is to provide a conveniently portable apparatus, by means of which the ends of ropes and cables may be securely held while being spliced, and also to provide means whereby sufficient pull may be exerted on the spliced strands to draw them into position in the splice

Heating and Lighting.

MATCH.—G. W. CURTISS, Blackwell, Wis. This match is a substitute for the wooden one and usable in the same manner by striking against any friction surface. A solid metallic body is provided having at its forward end a pocket extending axially a short distance, producing a tubular formation at the striking end. In this pocket is packed an absorbent such as absorbent cotton saturated with kerosene or other inflammable fluid. Over the end of the filled pocket and the end of the tubular shell thereof is affixed a striking head to cover the absorbent and shell in a way that the composition constituting the tip firmly adheres to the absorbent and to the shell, more particularly the former, by filling the interstices of the filling at the forward end of the pocket. The upper sketch is a perspective view and the lower a longitudinal section

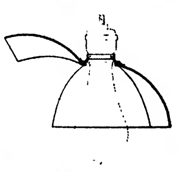
METALLIC MATCH.

ALARM SOUNDING DEVICE.—R. A. GASCH, R. F. D. No 1, Box 168, Seattle, Wash. The object of this inventor is to provide a device which will in all cases sound an alarm when the pressure communicating therewith falls below or rises above predetermined points, the device being so constructed that the alarm may be sounded at any points desired relatively to the device. Another object is to provide in connection with the said device means to afford communication with the atmosphere to reduce the pressure when the pressure reaches a point where the alarm is sounded The illustration shows a side sectional elevation of the invention, showing how it is connected with the boiler.



ALARM SOUNDING DEVICE.

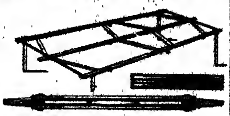
LAMP SHADE.—N B. MCGHEE, Clifton Apts, 231 N Broadway, Los Angeles, Cal The object of this invention is to provide a shade for lights or lamps, more particularly for incandescent electric light bulbs, so constructed and arranged that it may substantially or entirely conceal the light, or be adjusted to reflect the light downward, or while shading the greater portion of light, enable the light to be projected and reflected in a particular direction. The device may be used for warming hands; or in the sick room, placed in bed for warming feet and other parts of the body. Hospitals will find this shade of value in doing away with paper pinned around lamp bulbs The engraving illustrates one of the wings raised to reflect light in a particular direction.



LAMP SHADE.

Household Utilities.

CURTAIN STRETCHER.—H. MORLEY, 15 Edwards St Patchogue, N. Y. This stretcher is arranged to fold with a view to provide a comparatively small bundle for conveniently storing the stretcher when not in use and to allow quick and accurate adjustment to accommodate curtains of different sizes. For this, use is made of side rails, adjusting bars intermediate the said side rails, pairs of links connecting the adjusting bars with said side rails, slides slidable on the adjusting bars, and end spacing bars pivotally connected with the said slides and adjustably connected with the side rails to hold the latter spaced the desired distance apart. The engraving shows a perspective view of the stretcher extended ready for use; a plan view of the stretcher folded; and a side elevation with the parts in folded position.



CURTAIN STRETCHER.

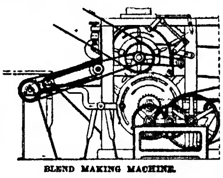
COVER FOR IRONING BOARDS.—T. M. BROOKMAN, 762 Spaulding St., Elmira, N. Y The intention here is to provide a cover for an ironing board arranged to permit plain ironing, ironing of filagree or lace, and to allow of readily placing the cover in position on the board or removing it therefrom.

Machines and Mechanical Devices.

ADDING COUNTER.—W. F. MULLANEY, Box 685, Marshall, Minn. This device will accurately measure the travel of a reciprocating element. In counters now in common use, it is not possible to accurately measure the travel of a reciprocating body, such as a piston rod of a pump, due to the fact that the counter does not register until the entire stroke has been made.

AIR WASHER.—M. S. KING, care of Wells & Newton, Ave B, 17th and 18th Sts., New York, N. Y. The object here is to provide an air washer which will thoroughly cleanse and humidify the air used in heating and ventilating plants, the washer being constructed with a hollow shaft, supported at one end by the shaft in the blower, which is freely disposed in the hollow shaft, which is disposed in and is keyed to the hollow shaft.

BLEND MAKING MACHINE FOR STAPLE GOODS.—A. I. GERRY, Sanford, Maine. By this mechanism mixing and blending are done with a minimum of hand work, the material being thoroughly intermingled and cleaned during operation, the action being such that the material is fed into the machine in charges of predetermined size, these charges being admitted at intervals when various movable parts are in position for the charges to be taken in. Mixing and blending can be better done if the material is first operated upon in the mixing chamber and thence transferred to another mixing chamber and there operated upon under somewhat different conditions The view shown is a fragmentary side elevation, and shows the first mixing chamber and parts associated therewith



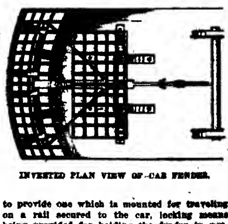
BLEND MAKING MACHINE.

Pertaining to Recreation.

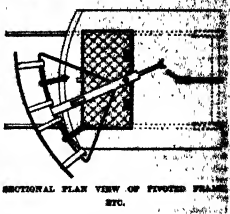
TOY AEROPLANE.—A. S. HECHT, 64 W. 88th St., Manhattan, N. Y., N. Y. This invention relates to toy aeroplanes, and the aim is to provide one which may be constructed at trifling expense, so that the aeroplanes manufactured in quantities, and may be given away for advertising purposes or to be sold for a few cents.

Railways and Their Accessories.

CAR FENDER.—C. B. MARTIN, Room 18, Cambridge Bldg., Portland, Ore. This invention relates to car fenders, and the object is to provide one which is mounted for traveling on a rail secured to the car, locking means being provided for holding the fender in normal position until it is pressed rearwardly, when the [illegible] fender is moved to the [illegible] in contact with the [illegible] pressed it rearwardly. [illegible] to assist in moving the fender [illegible] provides a pivoted frame [illegible] disposed in a horizontal position, [illegible] is permitted to drop when the fender is moved to either side. The first illustration shows an inverted plan view of the fender mounted on a car; and the second is a sectional plan view showing the pivoted frame, the apron disposed thereunder, the mat, and the means by which the last is connected with the pivoted frame.



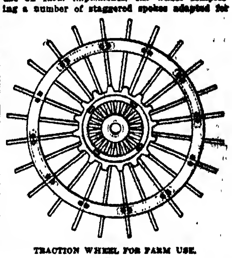
INVERTED PLAN VIEW OF CAR FENDER.



SECTIONAL PLAN VIEW OF PIVOTED FRAME, ETC.

Of Interest to Farmers.

WHEEL.—J. E. MCWILLIAMS, Hitchcock, Okla. This invention relates generally to wheels, and more particularly comprehends a traction wheel, especially intended for use on farm implements, for field work in especially plowed ground. The principal object is to provide a traction wheel especially adapted for use on farm implements, the wheel comprising a number of staggered spokes adapted for engagement with the ground whereby the implement may be drawn thereover. This invention overcomes the disadvantages following the use of a rim wheel; the wheel involves a number of radiating and staggering spokes adapted for engagement with the ground, thereby avoiding the packing of the ground after being furrowed by implements having flat rim wheels. The engraving shows a side view of the wheel.



TRACTION WHEEL FOR FARM USE.

Designs.

DESIGN FOR A LAMP CLUSTER.—J. D. ROSS, Seattle, Wash. This ornamental design for a lamp cluster when mounted upon a pole, standard or other support, presents an elegant cluster of five globes in a line, the upper three of which rest on a base, while the two remaining and outer ones hang from the ends of the form constituting the fixture. The three upper globes are somewhat larger than the lower ones.

NOTE.—Copies of any of these patents will be furnished by the SCIENTIFIC AMERICAN for ten cents each. Please state the name of the patentee, title of the invention, and date of this paper.

[illegible] on separate sheets [illegible] upon each mat[illegible] This [illegible] your ques[illegible] to be re[illegible] name and address [illegible]. No attention [illegible] queries. Full hints [illegible]nted from time to time [illegible]quest.

[illegible]asks: Can you kindly [illegible] what is the best heat insu[illegible]ly obtained for the insula[illegible]? A. No complete insula[illegible]. Wool is the best which [illegible]. Asbestos is good. Such [illegible]heat because they prevent [illegible] and thus convection cur[illegible]ansferring the heat from [illegible]urface. This is the phil[illegible] thermos bottle, in which a [illegible]en the glass bottle inside [illegible]outside.

[illegible]asks: Can a man exert [illegible] pull than his own weight, [illegible]osition that he may take? A. [illegible] steady downward pull on [illegible]rection, a man cannot pull [illegible]eight. He will then leave [illegible] himself into the air. He [illegible]reater downward force on a [illegible]eight by giving a jerk. By [illegible]d inertia he greatly increases [illegible]rope.

(12677) [illegible]M. A. asks: 1. Are there any theor[illegible]ed in regard to size and shape of an [illegible]ining an individual element, [illegible]each element, with a probability [illegible]ing a simple substance of matter? A. We [illegible] anyone holds that the size and shape of [illegible] determines the kind of matter [illegible] held by many that the difference [illegible] lies in the number of electrons [illegible]tain. The hydrogen atom, which is the [illegible], contains about 800 electrons. [illegible] hold this view will conclude that all [illegible]nts are derived from one form of mat[illegible] they would say that the parent of [illegible] that primal form. 2. Does not the [illegible] or atomic arrangement have the larger [illegible] the making up of an organic compound? A. [illegible] seems to be no reason for saying that the [illegible]arrangement is any more important in [illegible] substances than in inorganic substances. You will find two books of especial interest in this [illegible]: Duncan's "New Knowledge," price $2, and [illegible] J. Thomson's "Electricity and Matter," [illegible]1.25. From these books you will get the [illegible] view.

([illegible]2678) J. A. S. asks: As I have [illegible]ht almost everything I have read about on [illegible]construction of induction coils, have not yet [illegible] what is most essential; in fact, everything I have seen or read does not give enough information for the average amateur, leaving too much for the experimenter's imagination. I now have purchased 18 pounds of No. 36 wire and wound two coils carefully, one with cotton, the other with silk insulation. The cotton-wound coil has 46 double sections and the silk coil has 56 double sections, neither one giving more than a 6-inch spark. I do not know why, and cannot get the information anywhere. Possibly you could help me. Can you give me the address of some one or firm that I would be likely to get the information wanted? A. You have taken the very best course for finding the best method of making an induction coil, in buying Collins' book, which tells the whole story, from beginning to end, leaving nothing to the imagination. We cannot refer you to any better source of information. No firm making coils will give you advice. An induction coil is the result of an evolution by experiment. The man who has produced a form which gives good results will not publish the points in which his success lies. The book by Collins is the first effort to cover the subject of design for all sizes up to a coil giving a 12-inch spark. We think it quite reliable. Of course, there are many variations from his design, which might give good results. It is an old rule that you ought to get an inch of spark for each pound of secondary wire. Your coils are not up to this.

(12679) W. C. B. asks: As a disinfectant (inexpensive) for garbage can is air-slaked lime effective? Does it become inert when exposed to the air? Is charcoal a deodorant? What is your opinion of this formula: 3 pounds iron sulphate, 3 pounds slaked lime, 4 pounds road dust? A. Chloride of lime is a much better disinfectant than air-slaked lime for a garbage can or other domestic use. Charcoal acts as a disinfectant by absorption. It takes gases into its pores and thus removes odors from the air. If the charcoal is then burned the bad gases with their odors are destroyed. In the formula which you send iron sulphate is the active material and is one of the best disinfectants. The road dust serves simply as a vehicle to carry the iron sulphate. The slaked lime has some value but not so great value as many other [illegible]. For many formulas of high value for disinfectants we would refer you to our Cyclopedia of Receipts, price $5.

NEW BOOKS, ETC.

The Sun. By Charles G. Abbot. New York and London: Appleton & Co., 1911. 12mo.; pp. xxv, 448. Price, $2.50.

This is a book that was needed, and it has been written by the right man.

Hitherto the standard work in English on this subject has been Prof. Young's "The Sun," the latest revision of which appeared sixteen years ago, and is now out of print. Since it was published, at a time when solar physics was just beginning to be recognized as a field of research worthy of the whole time and attention of a numerous body of workers, this branch of science has made great progress, the record of which is scattered through a long file of the *Astrophysical Journal* and other kindred periodicals. Building upon Young's admirable treatise as a foundation, Mr. Abbot has given us a most welcome digest of all that is known to-day concerning the sun. As to the competence of the author, probably few of our readers will need to be told that he was Langley's assistant at the Smithsonian Astrophysical Observatory, and now, as director of that institution, is the world's foremost investigator of the problems of solar radiation.

The book is quasi-popular, i. e., it avoids the intricacies of mathematical physics on the one hand, but on the other can hardly be read to the fullest advantage by our friend in the street. The following are the chapter heads: I. The Solar System. The Sun's Distance. Its Dimensions. II The Instruments and Methods Used in Solar Investigation. III. The Photosphere. IV. Eclipses and the Outer Solar Envelopes. V. Sun-spots, *Faculæ and Granulations.* VI. What is the Sun? VII. The Sun as the Earth's Source of Heat VIII. The Sun's Influence on Plant Life. IX Utilizing Solar Energy. X. The Sun Among the Stars.

Comparing Abbot's book with the earlier literature on the subject available to persons who read only English (Pringsheim's "Physik der Sonne" has, of course, brought the matter fairly up to date in German) we find that a great deal of information formerly given in a vague and tentative way, is now stated as *res judicata*. The spectro-heliograph, for instance, has cleared up a great many problems The solar constant—which is fundamental in meteorology and geophysics, and the exact determination of which has been an urgent desideratum of these sciences—is at last definitely stated to average 1 95 calories (it is subject to some fluctuations) and Abbot's own work makes this value completely trustworthy All other existing reference books and text-books in English give either a considerably higher value, or present the values obtained by numerous investigators, ranging from 1 76 to 4 06, leaving the student very much at sea as to the most probable one.

Recent advances in the measurement of solar radiation have, of course, been conditioned by the improvement of pyrheliometric apparatus, and there is probably still some work to be done in this direction. The author gives us a description of the Angström instrument—which was somewhat rashly adopted a few years ago for official international use—and of course fully describes the more satisfactory types of instrument for which he himself is responsible; but does not refer to the Marvin pyrheliometer, now in use by the Weather Bureau—possibly because Prof Marvin himself has not yet published an account of this as yet unperfected instrument. Since Mr. Abbot's book was written Prof. Humphreys, also of the Weather Bureau, has announced that he is at work at still another instrument of this class

The chapter on "The Sun's Influence on Plant Life" discusses an important subject which was not touched upon in Young's book, and concerning which there is a dearth of popular literature. From the interesting account of solar engines, solar heaters, and kindred devices we learn that "excepting the solar heaters for bath purposes commonly installed in the roofs of houses, it does not appear that appliances for utilizing solar heat are yet introduced with economical success." Nevertheless, the author is quite hopeful on this subject.

The book abounds in minor typographical errors. Good proofreaders appear to be scarce nowadays in American printing offices. We fear the author himself must be held responsible for misspelling Leverrier's name four times on one page.

Reinforced Concrete Construction. In Theory and Practice. An Elementary Manual for Students and Others. By Henry Adams and Ernest R. Matthews. New York: Longmans & Co., 1911. 8vo.; 316 pp.; illustrated. Price, $3.

A short history of reinforced concrete paves the way for an intelligent study of theory and practice. The theory is confined to such principles as have a direct bearing upon actual conditions and requirements, and the mathematics of the work are kept within the strictest possible bounds of simplicity. Among the special constructions discussed may be mentioned retaining walls, bins and bunkers, chimneys, reservoirs and tanks, culverts and conduits, swimming baths, public shelters, underground lavatories, railway bridge work, wharves, jetties, and sea walls, and factories. Both American and English examples are usually cited and the numerous cuts are classified and grouped under the various branches of construction, so that each branch graphically presents a variety of typical forms. The work is on the whole admirably adapted to aid the beginner to a knowledge of real conditions, requirements and methods.

Concrete Costs. Tables and Recommendations for Estimating the Time and Cost of Labor Operations in Concrete Construction and for Introducing Economical Methods of Management. By Frederick W. Taylor, M.E., Sc.D., and Sanford E. Thompson, S.B. New York: John Wiley & Sons, 1912. 8vo.; 709 pp.; illustrated. Price, $5.

In estimating costs, the method advised is that of dividing each kind of work into a series of elementary operations, of timing and recording each of the "unit times," and finally of adding together the results in order to obtain the cost of the job. Tables are given showing just how long a workman should take to do a particular task—tables which have been obtained only after most exhaustive tests with the stop-watch on actual work Each piece of work in a trade has been reduced to its minor details; the efficient movements of the workman have been isolated from the inefficient and unnecessary; and each elementary movement has been studied with the stop-watch in hand The series of movements have then been grouped, the unit times summed up, and a sufficient margin allowed for unavoidable delay and accident Finally, the classification and tabulation of the data has been so carried out as to make practical reference to them a simple and sure matter The architect, engineer, contractor, superintendent and foreman will all appreciate the help here extended.

The British Journal Photographic Almanac and Photographer's Daily Companion. 1912. New York: George Murphy, Inc. 8vo.; 1,436 pp.; illustrated. Price, paper, 50 cents; cloth, $1.

This guide, philosopher, and friend of the photographer comes to us this year as multicolored and as corpulent as ever The enormous sections devoted to advertisements are bewilderingly kaleidoscopic .They contain some good pictures whose merits are credited to various lenses The almanac proper calls particular attention to the dates connected with the history of photography —the births and deaths of its great men, its discoveries, inventions, and processes. The reference section has too much matter for a satisfactory summary here, but includes among other things of interest to American readers an epitome of progress for the past year, hints on the management of studios, recent novelties in apparatus, the developing formulas of the principal plate and paper manufacturers, and some useful tables

Penrose's Pictorial Annual. The Process Year Book. Edited by William Gamble. Vol. 17, 1911-1912. New York. Tennant & Ward. 4to.; 305 pp Price, $2.50.

Those who have seen former volumes will take up this current issue with a pleasurable thrill of anticipation, and there is little chance of their feeling any disappointment. What very little indifferent work is exhibited is so buried in a mass of highly meritorious reproductions that it would be hypercritical in us to resurrect it A reproduction of the Mona Lisa forms the frontispiece of the volume, and thenceforward mellow collogravures, rich autochromes, restful monotints, and bright kinemacolors elbow one another for space between the covers. The wealth of pictures should not lead us to neglect the text, however There are many papers full of suggestion, information and help "Photography and Aeroplanes," "On Making Line Drawings from Photographs," "A New Style of Retouching in Machinery Illustrations," "Thoughts of an American Printer," "My Impressions of Kinemacolor"—these few subject-headings will show the diversity and scope of the discussions. No one who professes to keep in touch with illustration and process work can afford to ignore this yearly review, and it is worthy of a place on the table of the general reader and picture-lover merely by virtue of its splendid reproductions and its pleasure-bestowing power

The Locomotive. Vol. XXVIII. Hartford, Conn.: The Hartford Steam Boiler Inspection and Insurance Company, 1910-1911. Price, $1.

This bound volume of the little paper called *The Locomotive* contains all the issues of 1910 and 1911, and gives, among other things, a list of boiler explosions for each month, summaries of inspectors' reports, and articles and illustrations dealing with noteworthy explosions and the lessons they convey. An index is included which gives easy access to the miscellaneous information of the volume.

The Mechanics of the Aeroplane. A Study of the Principles of Flight. By Captain Duchêne. Translated from the French by John H. Ledeboer, B.A., and T. O'B. Hubbard. New York: Longmans & Co. 8vo.; 231 pp. Price, $2.25 net.

The name Duchêne will be familiar to those who have followed recent progress in aeronautics as that of an original and careful investigator of the laws and principles of dynamic flight While making no claim to having attained to more than approximate formulae, Capt. Duchêne has made accessible to the general reader and to the student a large body of knowledge concerning the behavior of aeroplanes under varying conditions. The mathematics used are purposely elementary, and all explanations and expositions assume only superficial knowledge on the part of the reader. The clearest possible wording is aimed at, and very generally attained. The four main divisions of the work deal with flight in still air, with the equilibrium and stability of the aeroplane in still air, with the effect of wind on the aeroplane, and with the problems of propulsion Among other useful tables are those for rapidly calculating the power required to fly an aeroplane, and for quickly finding the gliding slope. There is a summary of the chief properties of horizontal flight which will be most helpful to the student, and the chapter on the screw propeller is not the least important of the work. As a textbook, it will give the student a fair grounding in principle, and may save experimenters from many discouraging mistakes due to a failure to recognize or to properly take into consideration some necessary factor of a problem.

The Kingdom of Dust. By J. Gordon Ogden, Ph.D. Chicago: Popular Mechanics Company, 1912. 16mo.; 116 pp.; illustrated. Price, 50 cents.

One of the most fascinating things to children the world over is that of observing the Kingdom of Dust as revealed by the sunbeam In a somewhat speculative but none the less charming manner the author gives us the individual character of the inhabitants of this kingdom—the particles of musk, bits of iron and steel, scraps of leather, fragments of wood, cotton, silk, stone, gold, tin, wool, hair, paper, clay—in short, particles of every ingredient earth knows. His revelations will prove most absorbing to the young, and, aside from conveying instruction of real worth, must kindle in them a desire to pursue such studies further.

The Basic Open-hearth Steel Process. By Carl Dichman. Translated and edited by Alleyne Reynolds New York: D. Van Nostrand Company, 1911 8vo.; 334 pp.; illustrated. Price, $3.50 net.

The manufacture of steel by the basic process presents many problems which have thus far failed to bring forth adequate solutions The painstaking investigation of these problems by Carl Dichman is the basis of the volume in hand. He has first endeavored to establish conditions admitting of the complete utilization of raw materials in the best way This has entailed a vast amount of labor in quantitatively estimating the effect of all determining factors A lack of knowledge as to the conditions necessary to the economical utilization of fuel led him to devote his initial energies to the theory of gas producer working. The translator recognized in Mr Dichman's research a most valuable contribution to the science of its subject. The calculations are presented in minute detail, in order that independent investigators may check from step to step as they lead on and up to the eventual formulæ It is hoped that other investigators will use the data in this way, so that the fact or falsity of the author's premises and conclusions may be definitely determined, and the open questions which now vex the subject may receive something approximating to final and unanimous answers

How to Use the Microscope. A Guide for the Novice. By the Rev. Charles A. Hall. New York: The Macmillan Company, 1912. 12mo.; 88 pp.; illustrated. Price, 75 cents net.

The author has written several charming little books designed to conduct the tyro into the fields of Nature by the pleasantest possible paths, and in "How To Use The Microscope" he places the beginner under another debt of gratitude No attempt is made to describe other than inexpensive instruments and the preparation and elementary observation of common objects But within its particular scope the primer thoroughly fulfils its mission, and both matter and illustration are commendably attractive and informing

Key to Trees. By J. Franklin Collins and Howard W. Preston. New York: Henry Holt & Co., 1912. 16mo.; 184 pp.; illustrated.

This is an admirable little guide that will be hailed joyously by the tree lovers of the northeastern United States and adjacent Canada It is substantially bound, small enough to slip easily into the average pocket, and carries a wealth of illustration upon a very good quality of paper The identifications are for the most part based upon leaf characters, but a good cut of the bark is generally added Few technical terms are used, and these are defined in a glossary. The common names are given in full-faced type, the scientific names in italics There is also a systematic list of trees grouped in families, and a general index to tree names. The size of leaves is clearly indicated by an inch scale, placed beside each outline drawing, and six inches, divided into eighths, are marked off in gilt on the back cover of the book, so that comparisons may readily and conveniently be made

The Expert Wood Finisher. A Complete Manual of the Art and Practice of Finishing Woods by Staining, Filling, Varnishing, Waxing, etc. By J. Ashmun Kelly Malvern, Penn.: The Master Painter Publishing Company, 1912. 8vo.; 339 pp. Price, $3.

Maintaining that much of the charm of modern architecture lies in the use of natural woods, the writer endeavors to show how their rich variety of grain and coloring may be developed and preserved. The woods and the fillers used are described at length, and directions are given for ordinary finishing, for finishing and fuming oak, for veneer work, and for French polishing. Stains and staining constitute an important division of the manual, and a wealth of practical formulæ is presented Varnishes, their make-up, tests, and uses, is another capably-handled branch of the subject Instruction for renovating old furniture and on the treatment of stains and spots brings to a conclusion a very useful exposition of an important art.

VII.—Shall My Boy Become a Naval Architect?

By John Ritchie, Jr.

*[This is the seventh of a series of articles intended to set forth fairly the business possibilities of the technical professions. The articles are prepared by men who are connected with the more important technological institutions of this country and who are for the most part prominent educators. Because these teachers have instructed hundreds of young men in the principles of engineering, they are best qualified to write upon a subject so immensely important in the future development of American manufacturing industries.—*Editor.*]*

THIS was the question asked the other day of Prof. C. H. Peabody, head of the Department of Naval Architecture and Marine Engineering at the Massachusetts Institute of Technology. To him there have come young men, grown men, naval officers, from the nations of Japan and China that are developing their navies for the first time, and have sought the best instruction, the former being represented by an officer who was on the staff of Togo in the war with Russia, while no later than the school year that has just closed an ensign in the Chinese navy was one of his students with others of his countrymen. Then again the United States, recognizing the standing of the department that Prof. Peabody is maintaining, has made it a law that the graduates of Annapolis who are to become naval constructors must come to the Massachusetts Tech for two or three years for the finishing touches.

First, it seems worth while to note briefly what is meant by naval architecture and naval engineering. This is due to some of the changes continually effected in this busy world. When ships were of wood and the towering poops and forecastles of the three-deckers were susceptible of architectural treatment, the relation to architecture was self-evident. Now that ships are built of steel and crammed with machinery the relation to engineering is unmistakable. But at all times from its artistic side the designing of ships and especially of yachts, has never failed to appeal to those who consider the ship as something more than a mere conveying or fighting machine.

The adaptation of engines to ships, the increase in the functions that machinery are expected to fulfil, the growth in size and complication, and the more precise fitting of the vessel to its work have called more and more for a stronger grasp of principles by the architect as well as greater specialization by the engineer. And the story does not end here for the yards may be adapted each to its own work, some for warships, others for peaceful passenger greyhounds and others still for capacious freighters, while towboats, torpedo craft, yachts and motor boats are calling to-day for extended further specialization.

It may thus be seen that the field is wider than appeared at first, that there are opportunities in large number for the employment of technically trained men.

"The first reason why a young man should become a naval architect," said Prof. Peabody, "is because he wants to, but he must be intelligent, competent and willing to work." The suggestion of this successful professor followed the lines that the designer of ships and yachts, especially the latter, must have a combination of artistic sense and constructive ability, which will find its natural outlet in ship building. Such a person should be allowed to follow his natural bent. There are always a reasonable number of young men in the community who could be successful naval architects if not discouraged by parental caution.

"A second reason," continued Prof. Peabody, "is because there is a much wider field to which the graduates of such a department should go than the public realizes. Anyone who expects to have to do with the designing, building or managing of ships or building marine engines or motors for boats, will be better fitted if he takes a course in naval architecture and marine engineering." The fact is that this profession broadens the knowledge of the man who enters it. It is doubtful whether any other one calls for an intimate knowledge of so many different industries, for practically all the trades are represented in the modern ship. The design demands a knowledge of abstruse mathematics combined with data obtained from experimental work, and not the least important factor, particularly in the use of what are called "indeterminates," is that rare quality, good judgment, and this is developed by the study. Then the naval architect must be conversant with shop work in all its branches and with steel manufacture, foundry practice, steam engineering and electricity. It is indeed a broad education that is the foundation stone to success in naval architecture.

"Such a course combines the advantages of broad study in engineering," this leader in naval educational work went on to say, "including civil and mechanical engineering with the concentration on a special profession, and in particular the study demands all the advantages in the way of equipment that a large and powerful technical institute alone can furnish."

Then there is the advantage of close personal contact with the teacher in comparatively small groups of students. It must not be forgotten that although the ships of the sea represent the outlay of great capital, they can be counted as but small when compared with the enormous engineering enterprises of the land. It is, therefore, true that while the great demand for land engineers is scarcely supplied by the output in graduates of the great schools, relatively small departments and in comparatively few schools will suffice to supply the need for naval architects. There is room in the naval world for all who are now taking the course, there will be room in the future for an increased output, but there must always be the smaller groups of naval students and the consequent closer touch with the teachers.

Experience has shown that the work of the course really appeals powerfully to all young men who have any taste for the sea or for ships, and they evince an active interest in the work. "They learn to strive hard without feeling the tedium of uncongenial work. This of itself is a most valuable education, and many young men who have intended to go into business have taken the course because they liked it."

There must, of course, be considered the business opportunity for members of the profession. This, according to Prof. Peabody, is good. There has for several years been a larger demand for graduates than the school could supply, and this year there were two or three opportunities for each man who graduated.

Most important in the whole consideration is the fact that a brighter day for ship building has already arrived, and the future cannot fail to show an increase of opportunity. The men manning British shipping are now evincing great dissatisfaction with the miserable conditions of the present day and are likely to demand higher pay and other changes which will tend to lift the life to a level where it is possible for it to attract Americans, especially those who like that kind of life, and there are besides special futures for yachting and motor boating which already begin to cut important figures.

Provided he is intelligent, competent and diligent, for the young man who is willing to devote himself to his studies there are at this moment excellent opportunities in naval architecture and marine engineering, and these opportunities are sure to increase in the future.

INQUIRY COLUMN

Inquiry No. 9279. Wanted a machine for shredding asbestos board.

Inquiry No. 9280. Wanted names and addresses of manufacturers of machinery for stuffing dolls and teddy bears.

Inquiry No. 9281. Wanted to buy machinery for bleaching walnuts and ivory nuts.

Inquiry No. 9282. Wanted name and address of manufacturer of coin-controlled gasoline-dispensing tanks for automobile use.

Inquiry No. 9283. Wanted name and address of dealers in powdered Cocoa and Kola nuts in bulk.

Inquiry No. 9284. Wanted a plan for washing, screening and loading gravel for concrete purposes.

Uses of Cement in Sculpture

(*Concluded from page 196.*)

and the steel reinforcing tower, 8 feet in diameter, was built in its place. This tower ran the entire length and ended in a dome just below the neck, and was designed to support the head and shoulders of solid cement. Thirty-eight 1-inch twisted steel rods were cemented 2 feet into the solid rock with molten brimstone and red hot sand. This was done, not to anchor the statue, but to steady the steel reinforcing cylinder. Twenty-four rods were used in the circular tower; 14 anchor rods passed up through the folds of the drapery, joined the structure of the dome and then passed up into the head. This had to serve as a scaffold from now on and retain its form.

For the circular reinforcing ½-inch twisted steel rods and ¼-inch galvanized wire was used. The diameter of the tower was expanded, one wire placed on the inside and one on the outside, and twisted between the rods until tight, thus reducing it to its original diameter.

The solid concrete base (measuring 18 by 18 by 3 2/3 feet) was cast on November 10th. Maintaining a water supply was one of the chief problems of the work. The water had to be pumped up from the river below to a 5,000-gallon capacity storage tank, made in the ground near the statue, then lifted into another tank with an improvised water jet; here it was steam heated for mixing the cement.

An opening was left in the base below the ground, and six sections of the specially designed, collapsible metal inner forms, 7 feet in diameter, were taken in and set one on top of the other and joined together with taper dowel pins. Then on November 14th and 15th the pedestal was cast to within 6 inches of the figure.

Preparations were then made for casting the figure. An improvised derrick with grooved wheels was set over the mold with the hoisting tub working on the inside of the figure. The forms were taken off the pedestal and a chute put in to convey the cement from the mixer to the bottom of the shaft into the hoisting tub, and a small radiator was used to heat the inside of the mold. The first attempt was made to cast the figure on November 29th, but this was unsuccessful owing to inadequate preparations for zero weather.

It has frequently been asked why the final and most important work was not done sooner and in more favorable weather, or left until the following spring. It must be remembered that the whole operation of building a heroic statue in cement was an experiment, and could progress only as each new difficulty, which arose in connection with it, could be overcome. Delay in the material first used was perhaps the main reason for retarding work. Taking into consideration the action of freezing weather on water-soaked plaster, the prominence of the location of the statue, and the terrific wind storms which would sweep around it during the rest of the winter, it was imperative that the building be completed, to avoid a repetition of the first year's work.

Another 16 horse-power steam engine, four large tubular radiators, and one 20-foot steam coil were procured. A 30-foot gravel bin, 5 feet high, was made and the steam coil placed inside it, on edge. The four radiators were placed inside the scaffolding near the mold. The engine being considerably lower, everything was steam connected, and the pipes boxed, with return to the boiler. A system was also devised for warming the water which was being pumped up from the river. The whole construction was inclosed by canvas and sheet tin, all holes plastered shut, and after a final tryout the work began again on Tuesday, December 20th, 1910, at 5 P. M. The thermometer indicated 2 degrees below zero. Two crews of fourteen men each were employed for day and night shifts.

After all the preparation and trials it was a sight never to be forgotten—the two steam engines belching forth thick smoke and flame; the frozen chunks of

being thrown into the bin and shovelled out piping hot below; the water boiling, a full steady stream being pumped from the river; the hoisting signals; a typical western blizzard blowing; and above all, the men, contented and happy, working away with clocklike regularity, each at his assigned task.

The granite screenings were kept separate from the other concrete by inserting a row of tins 2½ inches from the mold; these were raised as the work progressed. When a form was full the lowest section was collapsed, hoisted and set on the top section until nineteen sections had been hoisted.

A large hole was cut in the back of the shoulders. The metal form (7 feet in diameter) for the dome was hoisted on the outside and slipped into place, the bucket was changed for outside hoisting, reinforcing rods for the dome were wired into place and a form was built between the dome and the window on the arms.

The work now progressed very slowly, so as to give the cement on the dome a chance to set and help support the thirty tons of solid concrete being placed above it. The only breakdown occurred at 3 A. M. on the last day of the work. With the temperature below zero, both engines suffered a temporary breakdown for half an hour, and all but froze the cement which was then on a level with the eyes. At this stage the cement was passed up in pails. On December 30th, 1910, at 2:45 P. M., the huge mold was full. Heat was applied for two more days and then the Spirit of Black Hawk, as the statue is often called, was left to the elements until the following spring.

I think the most exciting time in making a statue—and I am sure all sculptors and bronze founders will agree with me—is the moment when the mold is about to be chopped off. Will it come out perfect or not? Needless to say this part of the work had to be investigated as soon as the weather permitted.

In the early spring a party of three, Mr. Lorado Taft, Mr. Wallace Heckman, attorney for the University of Chicago, and upon whose land the statue stands, and I, investigated the result of our labor. I took photographs from a scaffolding as the piece-mold was taken off the head and shoulders. So far the result was entirely satisfactory.

Two weeks later the rest of the mold was taken off by splitting it from top to bottom and prying it off in huge slabs. At last there emerged a perfect—except for a few minor defects—monolith cement statue.

Practising Efficiency and Knowing Costs

Abstract of a Letter to a New England Manufacturer

By Harrington Emerson, Efficiency Engineer

DEAR SIR: In compliance with your request of last week, I give you herewith the substance of my remarks on practising efficiency and knowing costs.

In the operation of any undertaking one may attain high efficiencies and know little about costs, or one may know all about costs and practice no efficiencies. *Which is more important?*

When I was manager of a glass works I occasionally took Sunday dinner with a French glass-blower. Such meals for flavor and savoriness I have never eaten anywhere before or since, not even in the best restaurants of Paris, London and New York. The wife who cooked and served the meals was a French peasant woman, unable either to read or write. Her husband gave her $20 a month to run the table. She could scarcely count, so she would buy one thing at a time and pay for it, receive the package and change and then buy another item. She also had a garden full of marvelous vegetables and herbs. My! but she was efficient as to quality; she did not pay more than she ought in price nor did she buy table salt mixed with corn starch at $0.10 a pound when rock salt at $0.02 answered the purpose as well. My! but she was efficient as to quantity; she did not buy more than she needed nor did she ever use more than enough. This peasant woman did not know anything about cost-keeping, but she was a born and trained manager, practising that French thrift which has made the French nation one of the richest in the world.

I also knew a young American who had "system" on the brain. He subdivided his expenses under a great number of heads. He did not have a very large income—had to earn or beg or borrow it. He would pay any price that sellers asked, and he bought fourteen-dollar shoes when three-dollar shoes would have answered. He had twice as many suits as he needed, and he got very little use out of them. It was the same with food, with lodging, and with travel. On trains he paid extra fares, took the drawing-room, but spent most of his time in the buffet car. My! but he was inefficient; paying more than he should for everything, using higher qualities, buying more, using more than he should. Yet his accounts were beautifully drawn up in blue and red and green inks as well as black.

Which quality is more important in running a plant, *efficiency* or *system?*—the efficiency of the Scotch, the Quakers, the Yankees and the Swiss, or the system that balances up United States expenditures to a cent and spends in proportion to what it gets four times as much money as the Swiss Republic?

No doubt there are efficient French managers who know how to read and write and figure. No doubt there are systematic men who also practise efficiency, but the point I wish to make is that *efficiency and system are totally different and that efficiency is by far the more important of the two.* If I knew that every part of a plant I was managing was being operated at 100 per cent efficiency, detailed costs would be relatively unimportant. To know every cost, yet not know what the efficiency is, whether high or only 50 per cent, is as reckless as to run a steam boiler without safety valve or steam gage, trusting that it will not blow up.

Efficiency is the relation between *what is* and *what ought to be.* To determine what actual costs are is a clerical task, but this helps very little if we do not know what costs ought to be. Also, even if we are told what costs ought to be, it requires all sorts of skill to attain the ideal.

We may be running a foundry in which our castings cost $2.75 per hundred pounds. We may know that in another foundry similar castings cost $1.75 per hundred pounds. In such cases it is very usual for the superintendent to blame the equipment, to assert that if he had a new foundry with new equipment he could undoubtedly surpass the rival. It is also quite usual for the owners to blame the superintendent or the equipment and to advocate a change. Nobody knowing where or why the losses occur, everybody blames somebody or something else. If the where and the why are known, a thousand-dollar investment might cut the cost to $1.75. If the facts and remedies are not known, the emotional expenditure of $100,000 might run the cost up to $3 per hundred pounds. There is, therefore, a great difference between the relative importance of cost determinations (only a fraction of the efficiency principle of "Reliable, Immediate, Adequate and Permanent Records") and the skilled experience that can determine fair standards, and there is also a great difference between the analytical ability to determine fair standards and the executive ability and skill to attain them.

To illustrate from horse racing. The ancients five thousand years ago raced horses. Although it would have been very easy to have raced over a measured course and to have timed the speed by an

hour glass, a water clock, or by the beats of a pendulum regulated to an hour glass, it does not seem that even these elementary records, corresponding to cost accounting, were applied until about one hundred years ago. After thirty years of records as to trotting horses, one or two men who had given the subject life-long practical study set the extreme achievement of the trotting horse at two minutes. It took forty years more of intense refinement of track in shape and surface and banking, intense refinement of shoes and harness, intense refinement and improvement of sulky, intense and special skill on the part of driver as well as immense betterment in the physical welfare and training of the horse to realize two minutes out of the most carefully and selectedly bred horse.

Efficiency work is not overhead expense. It is a productive department whose motto is "Wealth from Waste." An efficiency department is inexcusable unless it yields in gain even the first year several times what it costs. If there is a big loss due to inefficiency, it may cost anywhere from $5 to $50 to rescue $100. If the plant is a small one the percentage of cost to saving is naturally higher than if the plant is a large one, though an efficiency scheme in its elements is essentially the same for the little plant as for the big one. Even if in a little plant an expenditure of $50 yields only $50 *net* profit, it is after all a remarkably productive investment.

The largest part of the value of the efficiency counselor is that he knows what *not* to do. If a chicken is put in a cage or maze from which it can escape only by taking one course out of a hundred, it will take it half a day of anxiety, of fluttering, before it accidentally strikes the right combination and gets out. If put back again it takes a shorter time to get out, and finally by not taking the wrong paths it makes its way out in a few minutes. Its improved efficiency is due to the omission of mistakes.

Any one can open a tumbler lock if he knows the combination. If he does not know it, the chances against hitting it by accident are many, and this alone constitutes the safety of the lock.

So, too, in efficiency work, there are a score of things that must not be done for every one that must. It requires thorough knowledge of efficiency principles and long experience in their application to know what "not to do," and in knowing these pitfalls lies success in applying efficiency principles.

Very truly yours,
HARRINGTON EMERSON

How Much Bread Will a Given Quantity of Flour Make?

FEW people, other than the bakers, have even the most remote idea of how much bread a barrel or any other quantity of flour should yield or how much more one brand will make than another. This is a much more important matter than the mere question of whiteness of the bread, or even of its real or apparent lightness. For some brands and lots of flour are much drier than other kinds, and will absorb much more water to bring them to the same degree of dryness as other brands, or other lots of the same brand. Further—and what is of much more importance—the quality of gluten contained in the flour, which is the more nourishing of the two principal constituents, determines much more largely than does the starch, the amount of water that the flour will take up. The best should be the cheapest, if the amount of bread made per pound under the same conditions is proportionately greater than the price demanded therefor. I happen to have on hand data concerning two well-known American brands, namely, "Gold Coin" and "Seal of Minnesota." From the former, a good baker or housewife can make about 345 pounds of dough per barrel of 196 pounds of flour, that is, 176 pounds of dough per 100 pounds of flour. Of the second brand, the figures at my disposition show 168 pounds of baked bread per 100 pounds of flour.

The Düsseldorf Exposition of City Building

By Our Berlin Correspondent

TOWN planning as an art is of quite recent date. In olden times towns were mainly shelters against the attacks of outside foes and accordingly were encompassed by walls into which the inhabitants of the surrounding districts would crowd on the approach of the enemy.

As there are now no walls to hinder the expansion of cities, and modern rapid transit systems permit of covering great distances quickly and cheaply, modern cities are seen to extend their suburbs like tentacles a long way into the country, deriving from the latter an inexhaustible store of vigor and health. The country used to come to the town; now the town goes out into the country. Moreover, the crowded network of narrow streets devoid of any trace of verdure is more and more replaced by regular systems of broad and well planned streets, leaving plenty of space for private gardens.

In view of the increasing importance attached to this problem the Exposition of City Building, organized by the city of Düsseldorf on the Rhine, would seem to be of more than passing interest. The idea of this exposition had been suggested by the decision of the City Counsel to call for a general competition for the building of Greater Düsseldorf, the outcome of extensive incorporations of neighboring communities. It may be said that Düsseldorf, the old and quiet town of art and gardens, had, with surprising rapidity, become an industrial center of nearly 400,000 inhabitants. It was intended to exhibit such plans of modern city builders as would be received in connection with this competition, but in order to avoid any one-sided presentation of the subject, the municipality invited all the more important communities of the western provinces to participate in a city exposition comprising all fields of communal life. This invitation was sent out to all townships having more than 10,000 inhabitants in Rhenania, Westphalia and Hessen-Nassau, as well as to some firms more directly connected with communal life. The Düsseldorf Exposition thus is a joint intercommunal enterprise of the towns and cities of Western Germany which in its conception is entirely new. About 600 exhibitors are showing nearly 4,000 different objects grouped under City Building, Sanitary Arrangements, Hospital Management, Civil Engineering, and Industry.

With its historical and modern town pictures, its models and photographs of remarkable monuments and buildings, old and recent, its reproductions relating to the designing of streets and drainage plants, gas and water supply, the exposition is nothing short of an illustrated history of German towns and is bound especially to appeal to those concerned with the character of modern towns and their manifold tasks from a social, educational and sanitary point of view.

The Department of City Building presents in 37 rooms a number of solutions of town-planning problems. The town of Hamm, Westphalia, illustrates by means of two relief maps corresponding to 1910 and 1916, respectively, the contemplated improvements of its street system entailed by the partial shifting of the river Lippe and the construction of the Lippe canal, the costs of this improvement work are estimated at $7,000,000. A large model illustrates the street improvement recently commenced in the Hansastrasse at Dortmund

Another scheme shown at the exposition, which is likely to arouse universal interest is the contemplated installation of a network of roads 21 meters (69 feet) in minimum width, affording a connection as straight as possible between the various centers of industry, and dealing with street car as well as carriage traffic. These roads are even to be continued beyond the industrial district proper, as far as Aix-la-Chapelle and Cologne and the Sieg district.

An important department coming under the head of "Sanitary Arrangements" is that of drainage plants and the purification of sewage Hamburg had long been the only German town having a well controlled drainage plant, until in the sixties of last century the towns of Frankfurt-on-Main, Stettin, Danzig, Berlin and others at last realized the importance of such installations

Included in the exposition are all the different systems of drainage, many schemes, general and specified, of plants of different dimensions on the mixing and separating systems, mechanical cleaning and settling tanks as well as plants designed on the biological and oxidation processes, special plants on the Emscherbrunnen system and some minor settling plants for industrial works, hospitals, etc

A kindred problem is the cleaning of streets and the refuse disposal The divers ways and means available in this connection are most adequately illustrated, thus affording to engineers a welcome opportunity of study and to the man in the street an interesting insight into a field yet insufficiently known The city of Dortmund, for instance, shows an installation for the collecting and loading of domestic refuse destined to be transported to some distance and for the cleaning of dust-bins on the alternating system. A large-scale refuse sorting plant connected with agricultural operation is exhibited by a refuse utilization company Pictures and actual models of refuse destructor plants are shown by some of the most important cities of Western Germany and by many engineering firms.

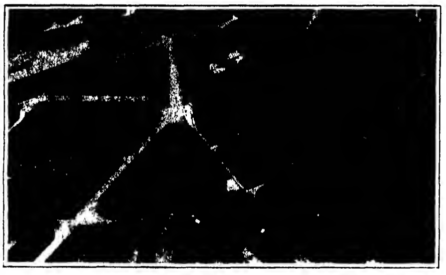
Communal and private hygiene, inclusive of the installation of baths, sanitary plants, heating, disinfection, school hygiene and other sanitary arrangements, constitute another department. Maps, illustrations and models of widely differing bathing establishments from the simple douche to the large swimming tanks and the most modern achievement, viz., riverside "beaches," are among the more important exhibits of this part of the exposition The economical and hygienical disposal of the dust of our dwellings has for the general health an importance which cannot be overrated.

Other exhibits of interest are those relating to the destruction of rats and gnats and on the other hand to the protection of animals The various arrangements for the treatment and prevention of disease form a special group showing in a most comprehensive manner the management of modern hospitals, as well as the provision made for the prevention of epidemics and the protection of infants

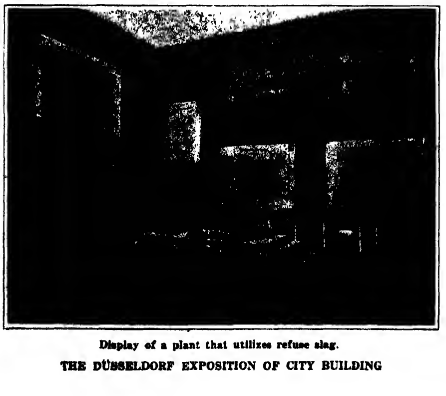
The department of Civil Engineering comprises plans and models of public and industrial buildings, railways, bridges, etc. The department of Industry finally reviews the development and status of the industry of Western Germany in its various branches and therefore resembles the ordinary industrial show

Exhibit of the municipal schools of domestic science.

Model of the city of Hamm and its environs.



Suggested plan for a town with plenty of garden space.



Display of a plant that utilizes refuse slag.

The Editor is always glad to receive for examination illustrated articles on subjects of timely interest. If the photographs are *sharp*, the articles *short*, and the facts *authentic*, the contributions will receive special attention. Accepted articles will be paid for at regular space rates.

The purpose of this journal is to record accurately, simply, and interestingly, the world's progress in scientific knowledge and industrial achievement.

Good Roads and National Defense

WHATEVER benefits of a military character may be derived from the recent army maneuvers (and they will doubtless be many) the operations have had the much desired result of drawing attention forcibly to the necessity for good roads as a part of the system of National defenses. The *Army and Navy Journal* states that there was one opinion shared unanimously by Army and National Guard officers who took part in the Connecticut maneuvers. It was that the roads of that State, with the exception of some of the main turnpikes, are not what the roads of so old and advanced a State as Connecticut should be. We are told that in the event of war and a heavy fall of rain, the side roads would be almost as impassable as the Virginia dirt roads were during the Civil War. The necessity for good roads is emphasized by the fact that the country is hilly; and those of us who have had occasion to travel through the State know that some of the hills are both steep and long.

The defensive maneuvers in Connecticut proved once more that good highways are absolutely necessary for the rapid disposition of troops. Napoleon understood this fact, and his system of military roads is one of the finest monuments left by this soldier-engineer. It is not to the point to say that railroads, which were unknown in Napoleon's day, are available now; for while the railroads are excellent for the conveyance of large bodies of troops quickly over long distances, we must remember that the majority of the movements of troops, especially in tactical movements, must be made over the State and country roads.

The Gordon Bennett Cup Race

IF the Gordon Bennett Cup race taught us anything it taught anew the lesson of America's backwardness in aviation. Prizes of ten thousand and fifteen thousand dollars had been offered by clubs for a cup defender. The response was discouraging to say the least. Gallaudet made a splendid effort to comply with the Aero Club of America's conditions by designing a machine which is in every way a credit to American ingenuity, but which sustained a severe accident a few weeks before the race. That a nation of ninety million people supposedly possessed of considerable wealth and interested not only in sports but in the most recent developments of mechanics should produce but one Gallaudet is hardly to its credit. But when that nation is more or less in honor bound to live up to the traditions of a Langley, who gave the world the first motor-driven aeroplane model, and of two Wright brothers, who gave the world the first man-carrying motor-driven flying machine, what can be said in defense?

To France belongs the credit of having displayed the greatest interest, not only in the Gordon Bennett race, but in the industrial side of aviation as well. From the very beginning the Gordon Bennett race has been a kind of milestone which marked the progress of French designers. True, in years past the race has been won by Englishmen and Americans, but the French really deserve the credit, for, with one exception their machines and their motors carried the pilot to victory. The only formidable competitors of Curtiss in the now historic contest of 1909 were a Blériot and an Antoinette machine. In 1910 the Blériot and Antoinette monoplanes were again in evidence, but improved in design and equipped with motors of higher power. In 1911 a Nieuport, a remarkable machine in every way, carried off the honors. This year the Frenchmen appeared on the scene with two Deperdussins of 140 and 100 horse-power, respectively, and a Hanriot of 80 horse-power. In the elimination trials held on July 13th last, these three machines developed amazing speed. The 80 horse-power Hanriot made 145 kilometers (90.09 miles) per hour; the 100 horse-power Deperdussin, 164.338 kilometers (102.11 miles) an hour; and the 140 horse-power Deperdussin, piloted by Vedrines, 169.81 kilometers (105.51 miles) an hour. Even the machines of Grahame-White and Hamel are French; for Hamel's monoplane is a true Blériot and Grahame-White's a Nieuport, for all its English pedigree.

It seems distinctly wrong to credit the man rather than the machine for a Gordon Bennett victory. Without disparaging in the least the courage and the skill displayed by the men who pilot monoplanes that cleave the air at one hundred miles an hour, surely it would be more fitting if the designer and manufacturer were to receive some of the credit. Why should not the rules stipulate that each country shall be represented not only by one of its citizens, but by a citizen seated in a machine made in that country?

A New Parcels Post

IT is gratifying to note that at last the Congress, before its final adjournment in August, passed almost unanimously an amendment (Section 8) to the Post Office Appropriation Bill (Public No. 336) providing for three kinds of parcels post, two of which are to have a weight limit of eleven pounds, and one a weight limit of four ounces, at different rates, to become operative January 1st, 1913.

The present parcels weight limit of four pounds is thus extended to eleven pounds, and conforms with that of several foreign countries. Fourth class mail matter is to embrace all other matter, including farm and factory products, not now embraced in either the first, second or third class, not exceeding eleven pounds, nor larger in size than seventy-two inches in length and girth combined, and not likely to injure in form or kind the person of any postal employee or damage the mail equipment or other mail matter and not of a character perishable within a period reasonably required for transportation and delivery.

The postal rate of this class is to vary in amount according to the distance the parcel is to go. This, we believe, will be the most vexatious and annoying feature of the new plan, and contrary to the purpose of our general postal usage, that is, one rate regardless of the distance traversed. The country outside of the Philippine Islands is to be divided up into units of area thirty miles square, which forms a so-called "postal" center, and postal maps or plans are to be put up everywhere showing the location of these numerous centers. The immediate place where the sending party happens to live is called Zone No. 1, and within a radial distance from the center of this zone of 50 miles a package weighing one pound or a fraction of a pound can be sent for five cents and three cents for each excess pound or fraction of same.

Zone No. 2 includes a radial area of 150 miles from the center of Zone No. 1, with a rate of six cents for the first pound or fraction of same and four cents for each additional pound.

Zone No. 3 includes a radial area of 300 miles beyond the center area of No. 1, with a rate of seven cents for the first pound or fraction of same and five cents for each additional pound or fraction thereof.

Zone No. 4 includes a radial area of 600 miles from the center area of Zone No. 1, with a rate of eight cents for the first pound or fraction thereof and six cents for each additional pound or fraction of same.

Zone No. 5 includes a radial area of 1,000 miles from the center area of Zone No. 1, with a rate of nine cents a pound or fraction thereof and seven cents for each additional pound or fraction of the same.

Zone No. 6 includes a radial area of 1,400 miles from the center area of Zone No. 1, with a rate of ten cents for a pound or fraction thereof and nine cents for each additional pound or fraction of same.

Zone No. 7 includes a radial area of 1,800 miles from the center area of Zone No. 1 with a rate of eleven cents for the first pound or fraction thereof and ten cents for each additional pound or fraction of same.

Zone No. 8 includes all territory from the center of area of Zone No. 1 beyond the 1,800 miles of Zone No. 7 and any portion of the United States, District of Columbia, Philippine Islands, and United States Territories at rate of twelve cents a pound or fraction of a pound and twelve cents for each additional pound or fraction thereof.

An appropriation of seven hundred and fifty thousand dollars was made to defray the cost of special equipment, maps, stamps, directories, etc., and the Postmaster-General is given authority to [illegible] the rates subject to the approval and consent of the Interstate Commerce Commission, [illegible] to insure sufficient revenue [illegible] cost of the service.

The Postmaster-General is also authorized to provide indemnification of shippers, for shipments [illegible] or lost, by insurance or otherwise, and [illegible] for the collection on delivery of the postage and price of the article sent, and to fix the necessary charges.

There is provided also a rural free delivery and local parcel post for delivery on a route from one person to another or to the central post office limited to a weight of eleven pounds for a single parcel with a rate of five cents for the first pound or fraction thereof and one cent for each additional pound or fraction of same.

The third kind of parcels post is unrestricted as to territory limits, and is general in its operation, but the weight limit is four ounces, and the rate is one cent per ounce or fraction thereof. This rate is the same as the existing parcels post.

There is no doubt of the success and value of this new parcels post legislation, and it will certainly advance the interests of all manufacturers throughout the country.

The International Congresses

WE had occasion last April, at the time of Dr. Eijkman's visit to America, to comment on the movement for internationalism in science. The subject is once more brought to public attention about this time by the meeting of no less than three important international congresses in this country within a period of three or four weeks. Of these, the first in chronological order is the sixth congress of the International Association for Testing Materials. The purpose of this organization is well brought out in the words of the opening address by Dr. Howe: "The function of the testing engineer is to stand between the public and the manufacturers who supply that public, to test the fitness of those supplies, to measure accurately their degree of fitness and to reject unsparingly the unfit. He is a guardian of those who travel by land or sea and of those who live or work in buildings of important size. He is the protector of the material interests of the public, because in the last analysis all structures and all materials of which they are made are for the use and benefit of the public, individually and collectively, and are paid for directly or indirectly by that public.

"To make this work of the testing engineer more effective, to guard the lives and the interests of the public, is the object of the association's existence. It is an open court in which the public sits in judgment on the various methods of testing."

An event which calls for our very special attention is the assembling in Washington and New York of the Eighth International Congress of Applied Chemistry. Something of the scope covered by this meeting may be gathered from the fact that the advance copies of the papers to be read fill no less than twenty-four octavo volumes. Some of the most significant of these will appear in the pages of our SUPPLEMENT. Yet the most important function of such a congress is not the presentation of papers, but rather the opportunity it affords for the direct interchange of ideas between the members attending.

And, thirdly, during the last week of September there will meet in Washington the Fifteenth International Congress on Hygiene and Demography. To say that the subjects treated are of vital importance is to use in a literal sense an expression which has become weakened by its over-frequent application as a figure of speech. After all, though in the mind of the technical man industry and commerce naturally are uppermost, these things are merely means to an end—methods of ministering to our welfare—and it is true for the community as for the individual that health is of greater importance than wealth.

The month of October also brings two international congresses to our continent. The Seventh International Dry Farming Congress will be held at Lethbridge, Alberta, October 21st to 26th, 1912. In connection with it will be held the International Congress of Farm Women. A feature of the meeting will be an agricultural show, comprising exhibits of farm products grown without irrigation under a rainfall of not more than 20 inches per annum. These congresses are attracting more and more attention throughout the world. To the sixth, held last year at Colorado Springs, thirty foreign countries sent delegates. Dr. John A. Widtsoe, president of Utah Agricultural College, is president of this year's congress, which will be the first held outside the United States.

It gives us, as Americans, no small satisfaction to [illegible] to the engineers, chemists and physicians [illegible] from all parts of the earth.

We see in this another sign that in the future America is to become a great center for the advancement of science, pure and applied.

Engineering

[illegible]—The proposed rack railway to [illegible], the [illegible] mountain health resort of the Philippines, is to run from Aringay on the coast via Galinao. A Swiss railway expert has reported favorably on the undertaking and it is hoped to have the line completed and in operation in two years.

The Question of Lifeboats.—The president of the British Board of Trade has appointed a departmental committee on boats and davits to report on the most efficient method of stowing, launching and propelling ships' boats. The committee invites inventors and others to submit suggestions by October 1st, 1912.

Gun-power Engine Economy.—Tests made by Prof. R. C. Carpenter of Cornell University show that the gun-power steam engine, using steam of about one pound above atmospheric pressure and a vacuum of twenty-eight inches, required about thirty-one and six tenths pounds of steam per horse-power per hour. This engine has been fully described in the columns of this journal.

Collier "Neptune" is Rejected.—It is stated that the collier "Neptune," built for the United States Navy under contract, has been rejected on the ground that she does not come up to the government specifications. This ship is fitted with turbines which drive the propellers through the medium of a mechanical speed-reduction gear. We understand that the reduction gear has shown excellent results during the try-out of the machinery; but that the failure to get good all-round results was due to the type of turbine employed.

Canal Open in 1913.—Replying to a communication from the Secretary of the Board of Harbor Commissioners, Los Angeles, Col. Goethals states, that every effort is being made to complete the excavation and the work on the locks of the Panama canal by June 30th, 1913. He expects to see the level of Gatun Lake at eighty-five feet some time in September, 1913. If this be accomplished and the first boat be successfully put through the canal, announcement will be made that it is in condition to pass shipping. This, the Colonel says, will allow of a year's try-out before the formal opening.

Six-inch Torpedo-defense Guns.—The return to the six-inch gun as the principal arm for secondary batteries is a noticeable feature of naval development in these days. When the "Dreadnought" appeared, the secondary batteries were abandoned and dependence was placed upon three-inch and four-inch guns for protection against torpedo-boat attack. Torpedo-boat destroyers, however, have increased so rapidly in size, that a larger gun is necessary to deal with them, and most of the navies have returned to the 6-inch piece; none are using less than the 5-inch or the 4.7 inch.

An Aerial Railway on Mont Blanc.—Aerial railways, which carry their passengers in cars suspended on cables, are the latest departure in the commercialization of the Alps. One of these unlovely but convenient devices is soon to be installed on Mont Blanc. Starting from Chamonix, at an altitude of 3,000 feet, it will ascend to the Glacier des Bossons at 7,500 feet, with two intervening stations. It will have a grade of 50 to 60 degrees. The line will finally be extended to the Aiguille du Midi, at an altitude of 11,500 feet. The first section is to be completed in 1913 and the extension the following year. The road will be worked with three cables—the carrier, the tractor and a cable for the brakes. Each carriage will accomodate 24 persons.

Railways in Morocco.—The Franco-German agreement of last summer concerning Morocco included a pledge on the part of these countries to construct a railway from Tangier to Fez. In general there are no engineering difficulties in the way of railway construction in Morocco and the cost is likely to be small. At present the only railway in the country is a small narrow-gage military line now nearing completion along the Atlantic coast from Casa Blanca to Rabat. All transportation between the coast and the interior is by caravan and is suspended in bad weather, as there are no roads of any sort away from the ports. Wheeled vehicles are practically unknown outside of Tangier and Casa Blanca, and the principal rivers intersecting the caravan routes are unfordable for several months of the year.

The Baro-Kano Railway, in Nigeria, recently completed, links Kano, the most important purely native center north of the equator in Africa, with Lagos, on the coast. The amazing statement is made in a recent consular report that prior to the opening of this railway most of the foreign trade of Kano was carried on by caravans across the whole width of the Sahara desert—especially between Kano and [illegible]—entailing a journey of some [illegible] months in each direction. This trade is now all [illegible] through British territory to Lagos by rail, and [illegible] to European ports—a total journey of [illegible] [illegible]

Electricity

Telephoning from Norway to Finland.—The Swedes are thinking of laying a telephone cable from Marieholm near Stockholm to Abo across the Finnish Bay. The Norwegians are very interested in this proposition as they could also communicate with Finland by telephone. It remains to be seen what the Russian authorities will say to this. The cost is estimated at one half million Finnish marks.

A 175,000 Volt Transmission Line.—On Big Creek, 275 miles from Los Angeles, a large hydro-electric plant is now being built. Current from this plant will be conducted to Los Angeles at a voltage of between 150,000 and 175,000. The gradual increase of voltage used on transmission lines in California is due to the low hygroscopic conditions of the atmosphere. It is predicted that before long voltages of 200,000 and 250,000 may be employed.

Silver-plating versus Nickel-plating.—The automobile industry says *Electricity* (London) is showing a tendency to supersede nickel-plating by silver-plating for the bright parts of motor vehicles. Nickel-plating, notwithstanding its hardness, has the disadvantage that when exposed to the weather it becomes coated with a film of oxide hard to remove. Silver has a whiter color, and is capable of a richer and finer polish. The surface does not peel or corrode, and when tarnished is far more easily polished. The labor cost of plating silver is no greater than for nickel, and as a very thin deposit is sufficient the greater cost of the metal need not correspondingly increase the total cost.

The Selenium Cell as an Aid to the Blind.—An instrument recently exhibited at the British Optical Convention enables the blind to use their ears to detect variations of light. There are a pair of high-resistance telephone receivers and a portable box containing a pair of selenium cells electrically connected to a battery and to the two receivers on a balanced Wheatstone bridge system. A clockwork interruptor gives an intermittent current which causes a rasping sound in the receivers, louder in that receiver and selenium cell circuit which is influenced by the stronger light. Thus a blind man equipped with the device in which one selenium cell faces toward his right and the other toward his left can sense the difference in light on the two sides, which may give him valuable guidance in walking.

The Edison Electric House.—Announcement was made in these columns some time since that Thomas A. Edison was fitting up a house in Llewellyn Park, New Jersey, with an independent electric lighting plant and a complete equipment of electrical apparatus. The purpose of this house is to demonstrate the advantages of electricity to the farmer who is so isolated, that he cannot obtain electric power from a central station. This house is now practically complete and will be open soon to the public. The current is generated by a small gasoline engine which drives a dynamo and the latter in turn stores the current in a battery of storage cells. The particular novelty of the system lies in the simplified means of control, so that the apparatus is rendered absolutely fool-proof and may be operated by inexperienced hands.

Russian Wireless Stations in the Arctic Sea.—Russia has for some time evinced special interest in the Arctic regions, sending out each summer expeditions to Nova Zembla and other parts of Northwestern Siberia, and taking up with renewed energy old plans of a ship connection between Europe and the Estuary of Siberian rivers. Russano, the well-known Russian traveler (in the company of Kushkine, who at the time was a member of Roald Amundsen's expedition) will set out in the spring for Arctic waters, in order, among other things, to find a navigable route to the rivers of Western Siberia. In order to improve and safeguard Siberian navigation, Russia contemplates the installation of radio-telegraphic stations on the northern coast of the Russian continent, as well as in Nova Zembla and other islands.

Bare Aluminium Wires for Coils.—The conductivity of aluminium is about 60 per cent of that of annealed copper. Accordingly, an aluminium conductor must be considerably larger in cross sectional area than a copper conductor if the two are to carry the same amount of current. Aluminium wire is always coated with a thin oxide which serves as an insulator. This insulation is enough, according to some European manufacturers, to permit of using bare aluminium wire in the coils of magnets. As the oxide film is of inappreciable thickness, a coil of fine wire thus constructed would be no bulkier, if as bulky, as a coil wound with insulated copper wire. H. F. Stratton, writing on this subject in the *Electrical World*, states that he has been unable to secure sufficient insulation when depending upon the aluminium oxide film as it naturally occurs in the commercial product. In order to increase this oxide, some European manufacturers wet the coil and then heat it. This he found hardly sufficient, but he has produced very successful results by passing the wire through sodium hydroxide, and then drying the coil by passing a current through it.

Science

Ciudad Porfirio Diaz exists no longer. One result of the new *régime* in Mexico of interest to geographers is the change of the name of this border town (opposite Eagle Pass, Texas) back to its earlier name, Piedras Negras.

Wireless in Siam.—A powerful radiotelegraphic station is about to be erected at Klong Toi, near Bangkok. It is expected to maintain communication with Penang, Singapore, Saigon, Hong Kong, and Manila. The vessels of the Siamese navy are also about to be equipped with wireless.

Prof. Parker and Mt. McKinley.—After an unsuccessful attempt to reach the summit of Mt. McKinley, Prof. Herschell Parker of Columbia University and Belmore H. Brown returned to Seattle on August 28th. It was found impossible to reach a height greater than 20,100 feet in the face of a blinding blizzard and with provisions nearly exhausted.

A New Telescope for Alleghany Observatory.—A 30-inch refractor valued at $150,000 was recently dedicated at the Alleghany Observatory in the presence of a distinguished company of scientists. It is said that the instrument was paid for by subscriptions collected for the last ten years. Among those who officiated at the dedication were members of the Astronomical and Astrophysical Society of America.

Coal Researches in Germany.—The new Kaiser Wilhelm science advancement institution is taking measures to found an institution at Mülheim for carrying on research upon coal and kindred subjects, with the co-operation of the large industries of this region. A large part of the expenses for the buildings will be borne by the municipality of Mulheim. It is also stated, that among recent German enterprises is the founding of an experimental therapeutic establishment at Berlin.

The Radiology Congress.—The sixth International Congress of Radiology and Electrology is to be held at Prague, from the 3rd to the 8th of October next, under the patronage of several Ministers. Prof. Stoklasa, rector of the Upper Technical School of Prague, will preside on this occasion. An exposition of apparatus of various kinds will be one of the features, and the delegates will have an opportunity to visit the Radiological Institute of Vienna and the radium laboratories of Joachimsthal.

Oldest Museum in the World.—Dr. Otto Kümmel, head of the East Asiatic Department of the Berlin Museum of Ethnology, tells of the oldest museum in the world, in the bulletin of the Société Franco-Japonaise. This museum may be found in the city of Nara, the former capital of Japan. Since its foundation, in 756, it went through all the changes of the Japanese Empire without one single addition to its collection. Dr Otto Kümmel is one of the few Europeans who were permitted to visit this museum. It opens its doors but once a year, on a day in spring, when a special committee inspects the collection, and a new list is made out. The museum contains about 3 000 articles, which are said to be the most beautiful specimens of decorative work, which have ever been produced by human hand, such as lacquer ware, decorative furniture, enamel ware, cambric like fabric, etc. The origin of the majority of the articles is uncertain; some came from China and others from Corea, but most of them appear to be of a more exotic origin. All, however, came of a time prior to the year 756.

The Work of a French Hospital Ship.—A recent consular report describes the remarkable work of the French hospital ship "Saint François d'Assise," one of two vessels maintained by the Societe des Oeuvres de Mer to minister to the wants of fishermen of the North Atlantic. The vessel in question cruises on the Newfoundland Banks, while her sister ship plies the Iceland fishing grounds and the North Sea. The hospital ship leaves France each spring and follows the French fishermen to the Banks. It carries a crew of 27 men, including a chaplain and a doctor, and has beds for 36 patients, besides accommodations for shipwrecked sailors and patients suffering with minor ailments. During the summer it speaks each fishing vessel on the Banks, without regard to nationality, to ascertain whether its services are needed. Sick or injured fishermen are given treatment, and when the cases are sufficiently serious are kept on board. From time to time the ship puts into St. Pierre to transfer patients to the French hospital at that place. During the year 1911 the ship steamed 12,209 marine miles, spoke 1,143 vessels, admitted 70 patients to the hospital, and gave treatment at sea in 420 other cases; besides picking up 14 shipwrecked sailors. The vessel also acts as a floating postoffice, under the authority of the French government, distributing and collecting mail on the fishing grounds. No charge is made for medical treatment or for medicines. Besides its two ships the society maintains two sailor's homes, one at St. Pierre and one at Faskrudsfjord, Iceland. It has a small subsidy from the French government, but is mainly dependent upon private subscriptions from year to year.

Grenadiers of the Air

Exploits in Bomb-dropping from Flying Machines

By Major H. Bannerman-Phillips

A grenadier was originally a soldier detailed and equipped for throwing hand grenades. He has long been obsolete. Only his name remains to recall his now historic function. It may be that the flying machine will rehabilitate him. Military men have been conducting experiments to ascertain just what is the destructive effect of explosives dropped from a height by a flying machine. In the campaign bombs have been dropped under actual war conditions. In France, Michelin offered a prize for bomb-dropping achievements, which was won by Lieutenant Riley E. Scott, an American. The following article, written by a British officer who is a recognized authority on the military uses of airships and aeroplanes, shows how much and how little may be expected of the new-fashioned grenadier of the air in the present state of our knowledge.—EDITOR.

THE first thing we have to consider in connection with the use of a flying machine or dirigible balloon for dropping projectiles is: Why we should use the machine for dropping them at all, inasmuch as a gun will send them with far more force and effect, and certainly with greater accuracy of aim.

The answer is that under certain circumstances we cannot produce the destructive or demoralizing effect we require by the aid of artillery, because we can neither see the objective of our attack nor calculate by map or otherwise its probable position with practical certainty; or because, although located by our air-scouts, it is at such a distance from our batteries that a shell will not reach it; or because our aerial destroyers must first locate the objects of attack, and having done so, must act on their own account with dropped projectiles. They would require to take such action when (A) the objective is out of reach of the artillery, (B) the moral effect of the attack (a stampede of cavalry or transport horses in their lines, for instance) can be achieved with a small expenditure of hand grenades, (C) the purpose of the attack is to effect the hasty demolition of buildings, bridges, or stores, by explosion or fire, but these latter are so situated, or so well guarded, as to be inaccessible to men landing from a flying-machine, and using explosives or other incendiary means at the ground surface, or (D) when the object of attack, say a column of troops caught on the march along a causeway or bridge, would get away into safety unless the aerial destroyer acted at once, instead of returning or sending word to the artillery.

There are roughly speaking four classes of targets or objectives against which the dropped projectiles might be used with advantage, other things being equal, and four separate types of bomb would be required for use accordingly:

1. Heavy explosive bombs.
2. Small bombs or hand grenades.
3. Incendiary projectiles.
4. Aerial projectiles.

It will be convenient, to begin with, if we take each type separately.

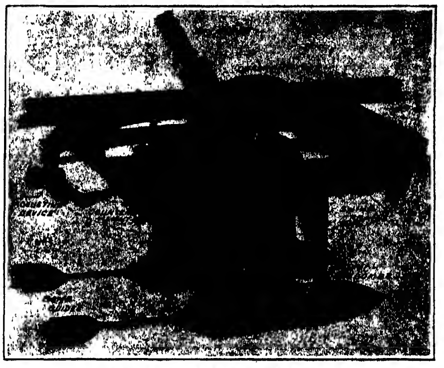
Heavy Explosive Bombs.

These would be used against such targets as dock yards, ships, railway junctions and termini, turntables, and rolling stock, bridges, postal, telegraph and wireless stations, banks, exchanges, telephone and staff offices, War Department and Admiralty buildings, range-finding bases of forts, and other nerve-centers generally. The demolition of these would tend to disorganize traffic (military and commercial) interrupt communication of orders and information, and thus paralyze the fighting forces of a nation, and bring pressure to bear on the civil authorities by cutting off supplies and starving the population.

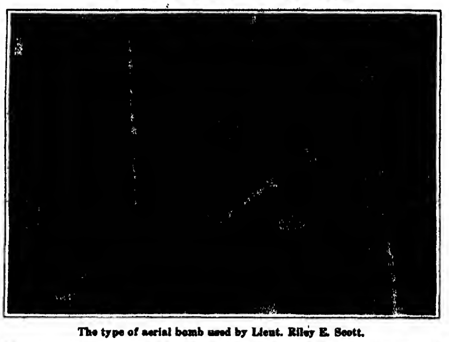
For such purposes as these the projectiles must strike the exact spot. Of the actual result of a charge of high explosive when merely *dropped*—not fired from a gun—and exploded on impact, we do not know much as yet, except that the effect, though great, is probably very local.

Hand Grenades or Small Bombs.

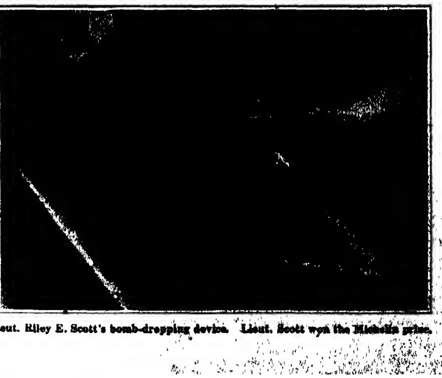
The second purpose to which dropped bombs would be put would be the attack of troops assembled in masses preparatory to extension or advance in small columns for attack; reserves kept in readiness for action under the shelter of high ground, whose position would be difficult to locate without overhead scouting, and against whom distant artillery fire could not therefore be used with certainty of effect; troops marching in columns of route along defiles and hollow roads out of sight of the enemy, but visible to the airman from above and unable to extend quickly to either flank, thus forming a helpless target to overhead fire; transport and ammunition columns on the march; convoys of provisions coming up from the base of supply in the enemy's country to the troops fighting at the front, these convoys being too far off to be reached by artillery and too well guarded in front and flanks to be open to attack by mounted troops moving on *terra firma*; horse-lines, and camps of all arms, the frequent harassment of which by bombs at night would stampede the horses, disturb the well-earned rest of tired soldiers, wear them out, demoralize them, and destroy their nerve.



An instrument for directing bombs from aeroplanes.



The type of aerial bomb used by Lieut. Riley E. Scott.



Lieut. Riley E. Scott's bomb-dropping device. Lieut. Scott won the Michelin prize.

For these purposes hand grenades or small bombs would be sufficient, the aim need not be very precise, and a fairly large number could be carried by one flying machine.

So far the experience of the Italians in Tripoli tends to show that the moral and material effect on troops of bomb-dropping from aeroplanes by day is very small. It has even been said that in some cases the bombs did not explode, and that they were picked up and used against the Italians themselves later on. The latter, however, have not given up the idea, but have been carrying on further tests of the effect of dropped projectiles from dirigibles in Italy and off the coast. Other evidence as to the uses of the small bomb or hand grenade, as thrown from an aeroplane, is scanty and indecisive.

Incendiary Projectiles.

These would be long, hollow, metal cylinders, with solid sharp-pointed steel heads, and with a percussion fuse and a bursting charge in the head, behind the steel point, the remainder of the cylinder filled with an incendiary substance or possibly inflammable liquid, which would burn fiercely on being released by the charge. They would be so weighted and so furnished with flanges, answering to the feathers of an arrow, as to insure their falling head-on, without turning over in the air during descent, the object being to penetrate the roof or outer covering of a building, gasometer, oil-tank, or magazine, burst the charge inside and start a conflagration, or to cover a pile of stores or supplies with burning liquid. These would have to be accurately dropped or they would fail to achieve their purpose.

Aerial Projectiles.

The fourth class of target would be an enemy's aircraft, aeroplane or dirigible, traveling in all probability very rapidly in mid-air, and changing its altitude and direction from time to time in order to baffle the attacker, who to drop his projectile must rise above the object aimed at. There are, of course, projectiles which can be made to overcome the force of gravity and travel horizontally toward the target by their own powers, such as the "aerial torpedo" invented by the Swedish officer, Col. Unge, but for the present we are not dealing with any other than *dropped* projectiles. To damage or destroy a hostile aircraft by this means the airman could use an explosive bomb containing either an incendiary material or fluid, with time and percussion fuse, so as to burst after a given number of seconds, or on striking the target. The percussion fuse would have to be very sensitive, and the intention in this case would be to damage by shock of explosion and fire in the case of an aeroplane, or by explosion of the gas in the envelope of a dirigible.

The Grappling Iron.

Another class of projectile suited for use against either aeroplane or dirigible, though it can hardly be considered a

"bomb," is the javelin or grappling-iron, armed with hooks and blades for tearing and cutting the frame-work, wires, and covering material of an aeroplane, or ripping the envelope of a dirigible and releasing the gas. Dr. Barton, an English expert, has patented a bomb for aerial purposes, which is intended to combine the attributes of the explosive projectile with the ripping and tearing missile. It is of fish-like or stream-line form, with bluntly pointed head, largest diameter at the fore-end, and tapering away to a slender tail which is fitted with helical blades to impart a rotary movement, when dropped head down. The tips of the blades terminate in hooks or cutting-edges for tearing the fabrics of a balloon, dirigible or aeroplane. The bomb may be dropped or projected from a tube mounted on gimbals, and fitted with guides or gages to indicate and influence the angle of descent. A flat vane, like that of a weather-cock, may further be attached to the tail of the projectile by means of a swivel-joint, so that the bomb may rotate without rotating the vane which is normally in the same place as the longitudinal axis of the bomb, that is to say, when the bomb is allowed to fall vertically the vane is vertical and under ordinary circumstances, does not affect the direction of its flight to earth. On the other hand, this vane, at a pre-determined time, by the action of a spring released by clock-work, or a time-fuse, which burns a retaining cord, may be caused to assume a position at an angle with the long axis of the projectile, and acting as a rudder will deflect it from its initial direction more or less horizontally.

The walls of the bomb are perforated and into the holes are inserted peculiarly shaped bullets, which release two or more knife edges, when they are projected from the bomb either by one or more successive explosions internally or by centrifugal force. The bullets are assumed to fly out in all directions and, acting like shrapnel, materially increase the destructive area of the bomb. Further, an explosive may be used to burst the whole bomb and break it up into a number of ripping-and-tearing fragments of metal at any pre-determined time.

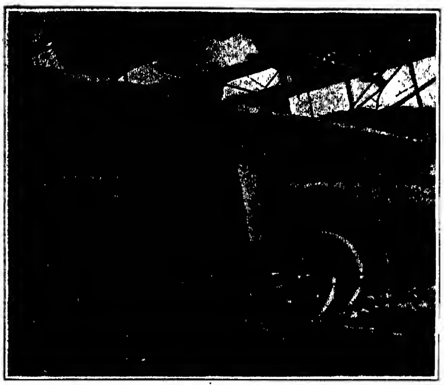
Having described the classification of objectives, which we are likely to attack by bomb-dropping or missiles from aircraft, it is as well to state that in all these cases it is understood that before commencing operations the attacker must be sure that his projectiles, if they miss the target, at least will not be dangerous to his own side. The summary of reasons for using the dropped projectile in preference to artillery, shows that usually these operations would take place over the heads of the enemy's troops or in an enemy's country, but in combats in mid-air between aircraft of any kind the rapidly changing positions of the latter might easily bring them both into the region immediately above our own troops or entrenchments, and we must be prepared to cease fire until the scene of conflict changes to a more suitable air-space.

So far, we have dealt with the dropping of projectiles in connection with the objects to be attained by the process and the kind of bomb or missile to be thrown.

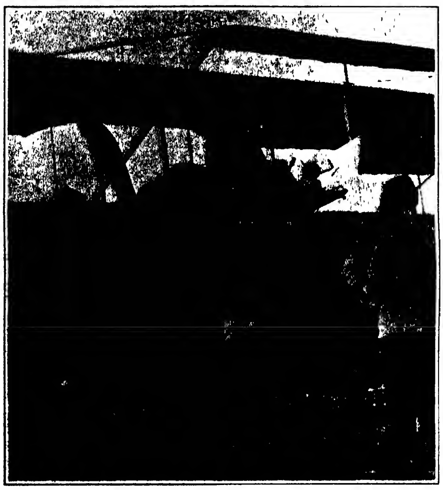
Hitting the Target.

We must now consider the means of securing accuracy in hitting the mark aimed at, and this is by no means so simple a matter as it would seem at first sight, or as it has frequently been represented in sensational literature.

First of all, we have to bear in mind, that however bold, and even reckless of their own lives, the occupants of an aerial machine may be in the interests of their own country and their own forces, they are hardly likely to approach the enemy by daylight unobserved, and an aeroplane is of little use—up to the present—by night. It follows that if they are to achieve their object before being themselves destroyed by artillery fire from below, they must keep at such a height as will give them the best chance of immunity, in spite of the target they offer,



The bomb-dropping apparatus employed by Lieut. Bousquet, who won second place in the Michelin contest.



Lieut. Bousquet seated in his aeroplane in which he competed in the Michelin bomb-dropping contest.

Lieut. Maillefer ready to start on a bomb-dropping flight. The bombs are contained in a trough.

while still able to see clearly what they themselves are aiming at. If the enemy also have aircraft, they have to keep a look out for these also, and though the enemy's gunners may possibly not fire for fear of injuring their own airmen, or their own troops below, by the spent shells and shrapnel, the would-be bomb-droppers cannot reckon on this, and must be prepared to become a target themselves at any moment, a friendly cloud being their only possible cover.

Now it has been proved by actual experience, that bullets from the enemy's rifles struck the aeroplanes of the Italian aviator in Tripoli at a height of 1,800 feet, and 3,000 feet as been suggested as a altitude, which it would be advisable for an airman to remain at, in presence of the enemy, in order to be reasonably immune from damage. This is not to say that he could not be reached by shrapnel or other projectiles, since there are guns which can throw their shell 10,000 feet and more, but taking into consideration the height of 3,000 feet combined with the pace, say 35 to 60 miles per hour, of an aeroplane, and its constant changes of altitude, it would be an exceedingly difficult mark to hit, and rapidly to judge distance on, in order to calculate for, and adjust the fuse, to burst the shell at the right place.

We must realize accordingly, that the bomb dropped from an aeroplane or dirigible has presumably to travel some 3,000 feet, say 1,000 yards, before reaching the object aimed at; that the aircraft is going at a considerable speed, and that the projectile consequently does not drop vertically on to the target, but describes a curve, the shape of which depends on the speed of the machine at the moment the bomb leaves it; that the projectile must therefore be released some time before the machine is vertically above the target, and that bomb-dropping, instead of being a simple matter, requires skill and considerable practice.

Besides this, some special form of sighting and dropping apparatus is advisable, and the bomb-thrower must give his whole attention to his work. If he is to achieve accuracy and economize ammunition he cannot act as pilot in addition. Even so he will find that, except in such cases as strewing hand grenades broadcast over a fairly large area, such as a camp, it is exceedingly difficulty to hit the objective and get satisfactory results. So thoroughly is this difficulty realized by those who have gone into the matter by the light of the little actual experience available, that it is considered, that in order to do any serious damage at the ground level from a reasonable height, there must be a number of flying machines in action and a plentiful supply of bombs.

The Difficulty of Aiming.

Viewed from this stand point the typical 'aerial destroyer" of fiction, setting out alone, but balefully efficient, to wreck ships and forts, strew death broadcast among troops, and decimate the population of a hostile township, and then bringing the recalcitrant enemy to his knees by the threat of continued destruction on the same lines, fades into the limbo of the extravagant and the impossible, but very serious possibilities still remain to be reckoned with, and it is worth our while to go into the question of sighting for the drop of a bomb and the means of release at the right moment.

The ideal method of attack would be to approach the vicinity of the target at high speed and slow down when within range, then hover immediately over it, sight the object through a telescope, drop one or any required number of projectiles through a special tube in connection with the sighting apparatus—and return to safety as quickly as possible. Such a plan as this might be feasible at night, in calm weather, with a dirigible, which can stop its engines and float noiselessly.

It is even remotely possible that it may be achieved with a heavier-than-air machine at some future time; for if we may

(Continued on page 229.)

The Flying Boat and Its Possibilities

How Safe Flying Over Water Has Been Attained and What It Means

By Carl Dienstbach

THE latest flying machine is an aeroplane that floats and runs on water, and that, at the will of the pilot, rises into the air and comes down to water again. This invention has opened new possibilities in flying because the hydro-aeroplane can stop and end its flight wherever a motorboat can be operated, and because it can be used as easily and as extensively as a motorboat. An aeroplane derives no support from the air unless it is quickly driven ahead. It must always start and land dead against the wind, and it needs, therefore, a clear level field of sufficient extent to begin or end its flight. Moreover, it can start and land only on a specially selected flying field. The great skill required to keep the aeroplane continuously in the air makes prolonged flying possible only for very experienced pilots. Even then a landing can be safely made only on a flying field. Pilots who fly at great altitudes across country always feel worried lest motor trouble should compel a landing. Even when gliding down from a height a suitable clear level field cannot always be reached. What appears as an inviting meadow from a distance may prove to be a swamp. Against his will the aviator may be compelled to alight at great risk. In great cross-country aeroplane races machines are often broken and passengers injured when they are thus forced to come down on unsuitable ground. The hydro-aeroplane that can alight on the water can come down everywhere and at any moment with perfect safety.

Early Attempts at Flying Over Water.

There are, in fact, so many advantages to be derived by starting and landing on water, that one wonders why the aeroplane was not originally a hydro-aeroplane. The first experimenters did indeed design their machine to start and alight on the water. Octave Chanute, who was the first engineer that had a clear conception of the difficulties of flying, urged all experimenters to try their apparatus over water, because "The worst that could happen to them there would be a ducking." Prof. Langley followed the same theory. Mr. Manley, who was on Langley's machine when twice it fell into the water, after being broken by the mechanical launching apparatus, undoubtedly owes his life to Langley's foresight. Maxim ran his purely experimental machine, with which he did not attempt any free flying, on a railroad track. Hargrave, Kress and Blériot made their early free flights with motor-driven aeroplanes provided with floats and started from water. The only exceptions were Lilienthal and Herring, neither of whom built aeroplanes in the modern sense, but rather wings which were so light that the aviator could carry them on his body. Archdeacon in Paris also mounted his aeroplane on floats and started it from the water, but his was only a gliding machine without motor or propeller, flown like a kite by towing it with a fast racing motorboat. Apart from all other considerations, the most elementary engineering principles would lead an experimenter to design an aeroplane as a hydro-aeroplane. A machine which has to move ahead before it can be supported in the air is, above all things, a vehicle with horizontal sails.

It was, in fact, a very definite necessity which finally caused Hargrave, Kress and Blériot to abandon the floating planes and to give us the swift aeroplane starting from a monorail with the aid of a catapult and landing on skids on soft ground. The necessity was most clearly illustrated when Glen H. Curtiss, the inventor of the first successful hydro-aeroplane, made his first experiments with an aeroplane mounted on water floats. Curtiss had every inducement to experiment with hydro-aeroplanes, and it is no doubt due to these that the world owes the invention of his useful type. The flying grounds at Hammondsport, where the Curtiss aeroplanes are built and tested, are small, but Hammondsport is situated on the shores of Lake Keuka, which would have offered an ideal flying field if it had been possible to start the machine from its surface. Consequently, in the fall of 1908, "June Bug," the first publicly demonstrated successful American aeroplane, was taken from its wheeled chassis and mounted on two canoe-like floats that resembled an ordinary catamaran. Although this was a machine that had flown well over land and that was far better equipped to get into the air than either the Hargrave, the Kress or the Blériot machine, it could be made to run quite fast on the water, but never fast enough to rise into the air. The reason is not far to seek. A speed that may be very fast for a water craft may be too low to start an aeroplane and support it in the air.

How a Flying Boat Should be Built.

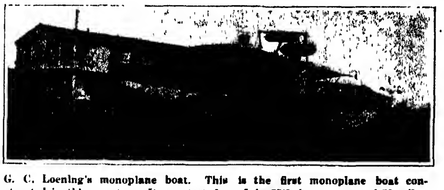
It is very easy to design a hydro-aeroplane on wrong principles. There are two ascending scales of effort that may be made to meet—then the hydro-aeroplane is successful—or which may not happen to meet each other—and then it is a failure, however well it may fly from the ground. The first scale is the constantly increasing head resistance of the floats in the water, which increases very rapidly with speed, and the second scale is the constantly increasing support of the planes in the air which also increases with the speed, but very much more slowly than the water resistance. This is due to the fact that what is fast in the water may be slow in the air, and that water resistance and air support both increase with the square of the speed. It is evident that the motor may exert its utmost power to drive a machine through the water with a speed that seems very fast, but that falls a trifle short of sufficiently supporting planes whose lifting power increases with the small squares 4, 9, 16, 25, 36, while the water resistance increases with the large squares such as 64, 81, 100, in spite of the fact that any appreciable lift would take the float partly out of the water and decrease the water resistance in turn. The result is that even a slight reduction of the resistance in water would enable a hydro-aeroplane to fly, which at a speed only a little lower, has practically no lift whatever. Obviously either a more powerful motor must be employed or the water resistance of the floats must be reduced. The four-cylinder motor that drove the first Curtiss aeroplane overland probably could not lift the present Curtiss hydro-aeroplane out of the water.

But the real solution of the problem—the real invention—lay in the design of the floats. This problem had already been partly solved in the hull of the fast racing motor-boats. Naturally, they were taken as models. A new principle was introduced, and that was the principle of the hydroplane, or gliding boat.

The Hydroplane Principle Offers a Solution.

The floats themselves had to be made to exert a lifting effort; the speed was increased to raise the floats out of the water by their own action. Thus the wings were enabled to exert their own lifting effect. In short, the hydroplane filled the gap between the two scales of effort mentioned. The moment Curtiss had found the proper shape for his flat-bottomed, rectangular-outlined float, the first practical hydro-aeroplane rose from the water.

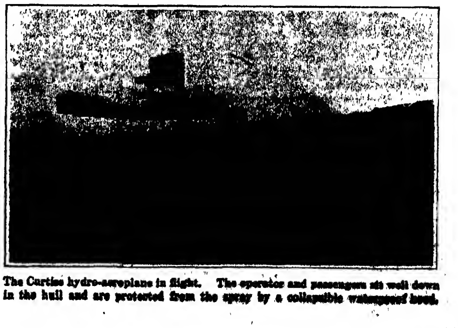
Curtiss, indeed, was not the first one to make a hydro-aeroplane rise at all. Fabre in France had anticipated him in that, but Curtiss gave us the first comparatively perfect machine. With the practical sense he has repeatedly shown, he recognized that one float has less water resistance for the same floating power than two floats, and that one float also makes the lateral balance of the floating machine more independent from the disturbance of the water level by waves than catamaran floats. He prevents his machine from capsizing by small auxiliary floats beneath the wings. He also has so shaped the floats that if by any reason or mistake of the pilot the machine should ever come down at a steep angle, the upper surface of



G. C. Loening's monoplane boat. This is the first monoplane boat constructed in this country. It was tested on July 25th in a voyage of 52 miles, during which occasional short flights were made.

The Curtiss boat is driven by an 80 horse-power motor. It is 26 feet long, 3 feet wide, and has a depth of hull about equal to the width. The planes are 5½ feet deep and 30 feet wide.

Lieut. Conneau's hydro-aeroplane in which he made some remarkable flights in France before he came to grief.



The Curtiss hydro-aeroplane in flight. The operator and passengers sit well down in the hull and are protected from the spray by a collapsible waterproof hood.

the float will not strike the water and thus overturn the machine by the tremendous resistance it would meet at its great speed.

There are at present very many types of hydro-aeroplanes. After the floats had been changed to hydroplanes nearly every type of aeroplane was transformed into a hydro-aeroplane simply by mounting it catamaran-like on two hydroplane floats that took the place of the ordinary wheeled running gear. But all these machines experience trouble if the water is rough. The single float type, on the other hand, leaps from wave to wave and starts at a light swell even in troubled water. Attempts are being made to make the hydro-aeroplane still more like a legitimate water craft by transforming it into a boat with wings. If that is done without impairing its flying qualities, it will certainly be for the better.

Even the best fliers have recently met with so many accidents while flying overland at great altitudes that ordinary men are afraid to take chances. Besides, there was always the necessity of starting from a distant flying field. As explained in the beginning, the hydro-aeroplane is not restricted to any flying field. Its shed may be erected on the grounds of any yacht club or preferably on a float anchored in the river. The shed may be floorless and the machine float like a boat on the water inside, sheltered from the wind. With its great speed and perfect obedience to rudders in the water, the hydro-aeroplane may run a long distance to a spot where the water is clear of traffic. It is not too big for a river; whereas the regular aeroplane is much too big for an ordinary road. It may run wherever a yacht runs, and withal the pilot has the pleasure of flying and of moving at high speed.

High Flying Not Essential.

Most important of all, the hydro-aeroplane, unlike the land machine, need not fly very high. It is only necessary to remember how even land birds skim the water. Flying is so much easier over water than over land because the conditions of the air over water are so totally different. Over water there is no dust, no obstacles to break up the air currents, no descending currents or air holes, and no ascending currents. The whole surface of the water is uniform in temperature. It does not heat the air and send it up in an invisible, dangerous whirlpool. In short, it may be said that near the water's surface the air is nearly as perfect for flying as over the land at great altitudes.

The whole surface of the water is one immense flying field, so that the hydro-aeroplane's pilot may come down and continue at a fast clip on the water and go up again whenever he pleases. Hence, even more or less inexperienced fliers, who have only learned to jump a few feet from the ground, may still take long excursions in a hydro-aeroplane. Too much, however, must not be expected from present hydro-aeroplanes. Obviously the floats of a hydro-aeroplane must be more like coasters than even the skids of an aeroplane. Skids are used only for a short run, but floats are required for long excursions.

Everybody knows that there is much wind over water. The planes must be pointed differently into the wind while running on the water than the floats are pointed in the water. This is something for designers to consider. The planes should be as adjustable as the sails of a yacht. But if a hydro-aeroplane is designed always to head automatically into the relative wind, like a weathervane, it will have no more to fear from squalls and storms than a motor-boat. It should also be built so strong that it will not be broken by a fall into the water from a moderate altitude, and its weight should be so distributed that in the water it will always regain an even keel and right itself again, no matter in what position it drops. If that is attained and the construction is strong, the hydro-aeroplane will be as safe as a dirigible (which it resembles because of its power of flotation). It may be upset, but it will always right itself again automatically upon touching the water and get into position to continue its flight.

The Coming French Maneuvers

THE coming maneuvers of the French army will see the application of the new ideas regarding aeroplanes and airships which were decided upon by the War Department. Each of the opponents in the maneuvers will be provided with an airship as well as a certain number of aeroplanes, and two airships will be held in reserve. To each party are allotted four fleets of aeroplanes or units of six aeroplanes each, making 24 in all, or 48 for the entire army. Each fleet is commanded by its officer. Aside from this there will be a number of aeroplanes put in service for artillery observations. On the whole, this year's programme is much more extensive than last year's, and the aeroplanes will be better organized as to supplies and repairs. For the first time there will be made an experiment in the use of aeroplanes for searching for wounded upon the battlefield, and Dr. Reymond, who is among the prominent military pilots, is in charge of this work.

Correspondence

Nitrocellulose and Wood

To the Editor of the SCIENTIFIC AMERICAN:

Under date of August 17th, 1912, you published an article that contained the statement that nitrocellulose solutions used as a varnish did not adhere well to wood. I have had ten years' experience in the use of materials used as varnish, and I know of nothing in this line that will adhere better.

About twenty years ago Mr. Goldsmith of the American Lead Pencil Company patented the idea of using nitrocellulose solution for finishing pencils. The idea was of great value, and Mr. Goldsmith successfully defended his patent, which is now expired.

Many hundreds of barrels of nitrocellulose solutions are annually manufactured and sold for use on wood by the concern which I represent. I am not seeking any free advertising, and my statements are merely in the interests of accurate information. There are many users of nitrocellulose solutions who well know that the statement that it will not adhere well to wood is inaccurate.

Futility of Dredging the Mississippi River

Editor of the SCIENTIFIC AMERICAN:

In your issue July 13th, p. 23, reference is made to the prospective use of the Panama canal plant upon the levee system of the Mississippi River "This would at once serve the double purpose of increasing the *flood capacity* of the river," etc.

Presuming that the flood capacity increase means the deepening of the river-bed and not the elevating of the height of the crown of the levees, I would state that in St. Paul, several years ago, a sand embankment was made from sand dredged from the river-bed of the Mississippi. How many hundreds of thousands of cubic yards were removed from the river-bed and piled upon the banks I do not know; but if I am correctly informed, the river bottom where the dredge sucked out the sand, like the muchly cursed Raven in Ingoldsby, "was not one penny the worse," as far as increasing its depth was concerned, and yet enough sand certainly was taken out to float the Mauretania in the displacement, and some other ships in addition.

Prof. Pinchot estimated that each year 400,000,000 tons of surface abrasion, call it silt, finds its way into the river, which, as it drifts along, helps to fill up a pot hole or two here and there.

Mark Twain, who knew the river quite well, and as a pilot had need to, remarked that dredging the Mississippi and keeping it dredged would be accomplished coeval with the time when Hades froze over. An indefinite proposition as to the fixedness of time and eloquently expressive of a negative result.

Point Loma, Cal. CHARLES CRISTADORO.

A Defect in Our Patent System

To the Editor of the SCIENTIFIC AMERICAN:

What seems to some a defect in the patent system appears to have been overlooked by Congressman Oldfield and other recent investigators. I say defect in the patent system, because while the defect appears in the procedure before the Patent Office, no remedy is suggested except through the change in the law itself.

I refer to the practice, that permits the issue of patent with claims dominating a prior patent without the prior patentee's having been afforded an opportunity of contesting the question of priority with the later patentee. This condition of affairs is found, when A issues a patent on limited claims, and B in an application pending concurrently with A's or filed subsequently to the issue of A's patent secures the issue of his patent with claims broader than A's. Suppose for instance, A shows one specific form of a generic invention and issues his patent on claims specific to his form. B then, after the issue of A's patent files his application for patent for a different specific form of the same generic invention and issues his patent subsequently to A's on broad claims for the generic invention by making oath to the completion of his invention prior to the filing date of A's application. B may delay the issue of his patent so long as to defeat A's right to a reissue or A may in other ways fail of reissue rights. How shall it be remedied? Possibly by providing special reissue privilege to A under the circumstances and by requiring, on the allowance of broad claims to B, that the patentee A, shall be notified and given the opportunity of filing reissue application containing the broad claims. Such notice might secure one of two results. In the first place, the patentee might assert a claim to the invention and file proper papers toward the enforcement of his claim. On the other hand, he might be in possession of some facts, which would show that the invention covered in the claims suggested and allowed to the subsequent applicant were not patentable, and in this way, the action might not only result in preventing an injury to a patentee, but, might also be of service to the public in preventing the issue of a patent for claims which were not, in fact, patentable.

Possibly some better remedy can be suggested. I do not feel capable of suggesting the full remedy, but only call attention to something that seems to demand remedial action. AN INTERESTED READER.

[In the case referred to, it appears that each inventor got what he claimed. Presumably each claimed what he invented, and so got all that he deserved.—EDITOR.]

Some Obstacles in the Way of Converting the Sahara Desert into a Sea

To the Editor of the SCIENTIFIC AMERICAN:

The idea of flooding 250,000 square miles of Sahara through a canal from the Mediterranean has some interesting features. You say that this area has 6,969,600,000,000 square feet. There are 525,600 minutes in a year. To put one foot of water over this surface in a year would require the canal to carry a little over 13,200,000 cubic feet of water per minute. As the evaporation in Sahara would probably not be less than five feet per annum the canal would have to carry 66,000,000 feet per minute to provide for this evaporation. A canal having a body of water 100 feet wide and 25 feet deep would provide for this if the flow was five miles per hour, but five miles per hour for an average would make a very swift stream in the center. Hence, the canal would have to be about three times as wide to prevent the banks from being washed away.

So far we have only provided for evaporation. To fill the 250,000 square miles to a depth of 200 feet in forty years would require a canal of twice the size or about 600 feet wide. If it were to be filled in less time it would be necessary to have the canal still larger. Of course the whole 250,000 square miles would not be covered at once, and consequently the evaporation would not be so great for several years, but the sands of Sahara are probably pretty thirsty and would probably absorb a good deal of water before any surface of consequence could be had.

But there is another view of the matter that is interesting. If the surface of Sahara is 200 feet below the ocean, then the lower parts of it might be filled to the depth of 100 feet and the remaining 100 feet be used as a fall to obtain water power. Assuming that 100,000 square miles would be covered in this way the canal would be required to carry 5,280,000 cubic feet of water per minute to balance evaporation. This quantity of water falling 100 feet would give approximately 1,000,000 horse-power. Assuming 50 per cent efficiency, 500,000 horse-power might be useful when sent over wires at about 100,000 volts. An inland sea of 100,000 square miles would probably be sufficient for ordinary purposes. But is the Sahara Desert as low as this, and is it possible to get any such thing?

Chicago, Ill. C. L. REDFIELD.

A Mathematical Card Trick

To the Editor of SCIENTIFIC AMERICAN:

The following is an old and interesting mathematical card trick, and perhaps some of your readers can explain why it works out.

From a pack of playing cards take out the jacks, queens and kings, leaving thus 40 cards. Now lay them face upward in the following order:

(Diamonds)	1	2	3	4	5	6	7	8	9	10
(Hearts)	10	1	2	3	4	5	6	7	8	9
(Spades)	9	10	1	2	3	4	5	6	7	8
(Clubs)	8	9	10	1	2	3	4	5	6	7

Next pick up the cards, one at a time, and lay them in a pile face downward, beginning from the right upper corner (10 of diamonds) downward to the 7 of clubs; follow with the next line to the left (9 of diamonds, 8 of hearts, etc.) and so on to the last card at the left lower corner (8 of clubs). Now spread the cards again, face downward, in 4 rows of 10 cards each, from left to right beginning with the card at the top of the pack (8 of clubs). The cards are now ready for performing the trick which consists in guessing the exact location of any of the cards, at the request of the spectators.

To work it out multiply the number representing the value of the card called for by 4 and add 3 for hearts, 6 for spades and 9 for clubs (nothing for diamonds). For instance, suppose the 2 of diamonds is called; 2×4 equal 8. The eighth card (counting from left to right, first upper row) is the 2 of diamonds. The 6 of hearts would be found thus: 6×4 equal 24, plus 3 equal 27; the 27th card, i. e., the 7th card in the third row should be the 6 of hearts, and so on. When the product plus the number added exceeds 40, count the excess from the first upper row again; for instance, the 9 of clubs should be 9×4 equal 36, plus 9 equal 45 (excess 5) the 5th card in the first row is the right card.

Mayaguez, Porto Rico. WILLIAM FALBE.

The Gnome Rotary Engine

The Airman's Chief Reliance

By Earle L. Ovington, Consulting Engineer, Licensed Aviator

Wonderful records for speed and endurance, for high-flying and passenger-carrying have been made. They testify mutely to the efficient motors upon which the record-breakers relied. Almost all of the more remarkable feats of the aeroplane have been achieved with the rotary motor—a type originally invented in this country but carried to perfection in France. In this article, written by a man who is not merely a noted pilot but also an engineer trained at the Massachusetts Institute of Technology, we are told what the Gnome engine means to the man in the air and to what its astonishing success is due.—EDITOR.

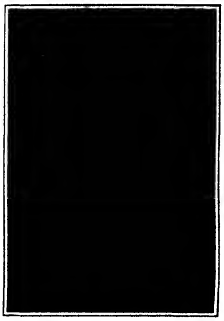

Fig. 1.—The cylinder blanks as they come from the drop-forging hammers.

Fig. 2.—First process of working the heavy cylinder blank—roughing out the bore.

Fig. 3.—Flanging a cylinder in seven and one-half minutes; the previous tool took nearly three hours.

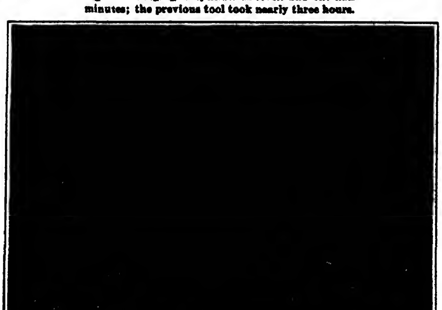

Fig. 4.—The process of finishing the cylinder head requires frequent regrindings.

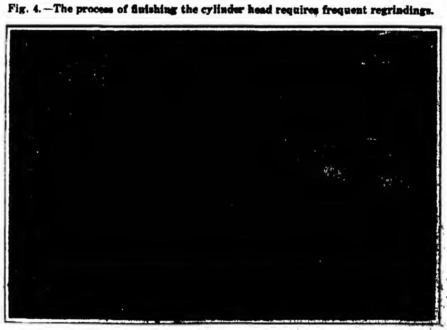

Fig. 5.—Grinding process in finishing, where a mirror-like surface is obtained in the bore of a cylinder.

ONE of the most interesting afternoons, if not the most interesting, that I spent in Paris was when I went through the well-equipped factory where the wonderful rotary Gnome engine is made Monsieur Seguin himself, the designer of the motor, acted as my guide so you may be sure that I saw about everything there was to be seen.

The spectacularly rapid development of the aeroplane is due, far more than even those in close touch with aeronautic affairs seem to appreciate, not so much to the improvement of the aeroplane itself as to the perfection of the motive power

In July, 1909, Blériot flew the English Channel, and his feat was heralded as almost miraculous. And, indeed, it was, as those can appreciate who are acquainted with the motor he employed for his epoch-making flight—a three-cylinder affair, which developed not over twenty-five horse-power at the most. I learned to fly at Pau, France, with the same type of motor and was forced to try three before I could get one which would remain cool long enough to carry me the short distance required in the flights for a pilot's license. And when I landed, the temperature of my engine was nearer that of an overheated stove than that of an efficient internal combustion motor The Blériot monoplane of to-day is practically the same as the one used in that memorable first Channel flight, and yet is capable of sustained operation across country as well as ideal for high-altitude work. In fact, the world's altitude record, made by Garros, was made with this machine. In the Boston *Globe's* Tri-state aeroplane race, I won the $10,000 prize by flying one hundred and eighty-six miles in three hours and six minutes, and when I landed my motor was in nearly as good condition as when I started

Why this difference between the monoplane with which Blériot was just able to fly the Channel, and the modern efficient plane of to-day? One word tells the story —the motor To be sure, aviators are more daring in 1912 than they were in 1909, but primarily, this is due to the fact that they know their mechanical birds are more dependable than formerly; and this dependability is largely due to the improvement in the motive power

If I were asked to give my opinion of the Gnome motor in as few words as possible, I should say that it was theoretically one of the worst designed motors imaginable, and practically the most reliable aeroplane engine I know of I should have to add as a qualification that I assume it receives the constant attention of expert mechanics. As I had two seventy horse-power, seven-cylinder Gnomes with my Blériot monoplane, and probably flew more miles last season with a Gnome motor than any other aviator in America, I speak from experience. If an expert engineer on gasoline engines were asked to examine a Gnome motor, one having no previous knowledge whatever of the mechanism, he would unquestionably pronounce it an impractical, though a highly ingenious construction. In fact, when the first Gnome shot meteorically into the limelight, this was the universal opinion in engineering circles.

You can hold a Gnome piston in one hand and break a piece from it with the thumb and finger of the other, the walls are so fragile. The valves are so thin and so large that you never cease to wonder why they are not warped out of shape before they have been in service three minutes. Literally, no piston rings are used, the "obturateurs" which serve the purpose being simply rings of thin sheet bronze, one to each cylinder. Compression in a Gnome is noticeable by its absence and, "of course," says the engineer upon first examining the engine, "the spark plugs would be rendered useless as soon as the motor attained its speed." This is what might be expected with the plugs situated in the cylinder heads of a revolving motor where a gallon of oil goes past them every hour of operation, but there is seldom plug trouble. Yet, withal, the Gnome motor is, in my opinion, in a class by itself where the greatest power for the least weight, together with reliability, is desired.

The Gnome is a very expensive motor to buy and to keep up. My seventy horse-power engines cost me $4,000 each, and I paid three French mechanics fancy salaries to act as trained nurses for the delicate mechanisms. *But I had the highest power motors for their weight, and that is what is wanted for exhibition work.* At the Chicago meet, I won the price of a motor in a couple of days' flying. Yes, I will acknowledge the Gnome is expensive to buy, expensive in upkeep and delicate in construction, but for speed and reliability, I have not found its equal.

"How can a delicate motor be reliable?" you say, and I do not blame you for asking, for such a statement seems paradoxical. Nevertheless, it is a fact. Let me explain. Usually every fifteen hours of running, and at most every twenty, my mechanics went through the interesting process of separating every single component part of my motor one from the other. The valves were reground and retimed, new valve springs were inserted, the tappet rods were adjusted, and the whole motor was given a rigid inspection. The Gnome, in common with most rotary motors, uses castor oil as a lubricant, hence at each cleaning great quantities of carbon were removed. I claim that any engine requiring such attention may rightly be termed "delicate." How far would you get in an automobile if you had to take the entire engine to pieces and readjust practically every working part of the whole motor every fifteen or twenty hours of service?

But—and this is the important part to the aviator who depends upon speed and

Fig. 8.—View picturing the finishing of the hollow crankshaft of a Gnome motor.

exhibition work for his remuneration—my Gnome motors never stopped while I was in the air, unless I purposely cut off the ignition, and—another consideration of equal importance—I had great power combined with light weight, which usually brought me in either the winner, or at least second man, in a race where perhaps the prize was $1,000 for a fifteen-minute flight. I made one hundred and seven flights in my Blériot and never broke a single stick in the machine, and I attribute my success largely to the fact that my motor never failed me in the air. I had several bad smashes, but in every case without exception these smashes were due to motor trouble, and they occurred when I flew a machine other than my faithful Blériot "Dragon Fly," which was given such careful scrutiny by my expert French mechanics.

The Gnome factory, situated on the outskirts of Paris, is not a large one, but it is unusually well-equipped and up-to-the-minute in operation. The very latest type of machinery is employed throughout, and wherever possible it is automatic to the last degree. This employment of automatic machinery of the latest pattern is not as common in France as in this country, and even in some European countries, for the French are proud of their handwork. Incidentally, the greater part of the automatic equipment is made in America—the home of the automatic machine tools. If we judge the character of a factory by the weight of its output, then we would have to acknowledge that the Gnome establishment turns out steel shavings, with motors as a by-product, since for every pound of motor manufactured, there are over ten pounds of shavings. There is not a single cast piece in the Gnome engine—every part is cut from a drop forging or from the solid metal. Fig. 1 gives an idea of the cylinder blanks as they come from the drop forging hammers. Each blank weighs in the rough no less than eighty-one pounds. This weight is reduced to four and one half pounds to make a cylinder for the lightest motor in existence, for its power Fig 2 shows the first process of working the heavy cylinder blank—roughing out the bore. Fig 3 depicts what was to me the most interesting process of all—that of flanging the cylinders. Thirteen cutters, working simultaneously, produce the most highly finished and most perfectly formed flanges I ever saw on a gasoline engine. You cannot look at the Gnome motor, and be interested in engine design at all, without being lost in admiration of the beautiful machine work as exemplified in the flange construction of the cylinders This flanging tool, Monsieur Seguin explained to me, takes just seven and one half minutes to complete its work on a cylinder, while its predecessor required almost three hours for the same job. "And," he added with a twinkle in his eye, "we had to go to Berlin for it—you Americans have nothing so rapid in operation." I replied that I noticed that most of his machine tools bore the name plates of American manufacturers, which indicated that if we could not make cylinders as rapidly as the Germans, we excelled in almost everything else. Fig. 4 illustrates the finishing process of the cylinder head The exhaust valve screws into the end of the cylinder and may be removed, complete with its seat, for the frequent regrinding necessary to efficient operation In Fig 5 the grinding process is shown After the cylinders are ground with the greatest care and accuracy, the finishing is carried still further by wearing-in the cylinder with an actual piston carrying an "obturateur" No pains are spared to obtain the mirror-like surface so noticeable when one examines the bore of a Gnome cylinder

Fig. 6.—Workmanlike job of welding the bushing into the side of the cylinder head by autogenous process.

The bushing into which the spark plug screws is not integral with the cylinder as in a cast construction, but is welded into the side of the cylinder head by means of the autogenous process as shown in Fig. 6 An unusually workmanlike job is the result A pile of completed cylinders is shown in Fig. 7. This engraving indicates plainly the enormous size of the hole in the cylinder head into which the complete exhaust valve is screwed. It is also evident that this construction enables the inlet valves to be easily removed, since these screw into the piston head. Both inlet and exhaust

Studying the Flying Machine in the Laboratory

Recent Progress in Experimental Aerodynamics

By A. F. Zahm, Ph.D.

As sundry detailed and unrelated accounts of modern aerodynamic laboratories have from time to time in current literature disclosed the equipment and manifold activity of these institutions, it seems advisable to have a general review of the aggregate recent development in the basic science of aerial locomotion; a review primarily of the physical results achieved, and secondarily, of the appliances and methods of investigation. No more competent scientist can be found in this country to write such a review than Dr. Zahm. He has conducted original studies which have done much to clear up some of the obscurer phases of the subject of aerodynamics, and what is more, has kept alive interest in aerodynamics by contributing admirably written and illuminating articles to the SCIENTIFIC AMERICAN *and other periodicals.*—EDITOR.

BROADLY stated, the men of the nineteenth century outlined the essential features of dynamic aerial transportation, and demonstrated its feasibility, but left to the twentieth century the arduous labor of establishing its commercial practicability. The pioneer efforts in this science comprise a long succession of valuable researches, made sometimes with simple models and sometimes with complex structures equipped for actual flight. The early methods of experiment and computation still obtain; but the old data and, in part, the old designs have needed revision, if not radical alteration. This work of refinement has occupied recent investigators no less laboriously than the making of new discoveries.

The developments of aerodynamics during the nineteenth century are of practical rather than philosophical interest. They furnish approximate laws and rough data for the engineer rather than explanations of phenomena through those intimate and fundamental relations so important to the mathematical physicist. The science of fluid dynamics must disclose not only the resultant effect on a body immersed in a medium having relative motion with it, but more especially the proximate cause of such effect, as determined by the velocity and stress at each point of the medium, both at the bounding surface of the body and in its neighborhood. The experimental investigation, however, of the velocity and stress of the air at all points about a model, though initiated in the nineteenth century, was, for thorough prosecution, left over to the succeeding one.
